Analysis of Kelly-optimal portfolios

PAOLO LAURETI, MATÚŠ MEDO* and YI-CHENG ZHANG

1. Introduction

The construction of an efficient portfolio aims at maximizing the investor’s capital, or its return, while minimizing the risk of unfavourable events. This problem has been pioneered in Markowitz (1952), where the Mean-Variance (M-V) efficient portfolio has been introduced: it minimizes the portfolio variance for any fixed value of its expected return. Since this rule can only be justified under somewhat unrealistic assumptions (namely a quadratic utility function or a normal distribution of returns, in addition to risk aversion), it should be considered as a first approximation of the optimization process. Later, several optimization schemes inspired by Markowitz’s work have been proposed (Sharpe 1964, Perold 1984, Konno and Yamazaki 1991). For a recent thorough overview of the portfolio theory see Elton et al. (2006).

A different perspective has been put forward by Kelly (1956), where he shows that the optimal strategy for the long run can be found by maximizing the expected value of the logarithm of the wealth after one time step. The optimality of this strategy has long been treated and proven in many different ways (Breiman 1962, Finkelstein and Whitley 1981, Browne 2000) and, according to Thorp (2000), it was successfully used in real financial markets. For an overview of its continuous time limit see Platen and Heath (2006). Recently, the superiority of typical outcomes to average values has been discussed from a different point of view in Marsili et al. (1998) and Maslov and Zhang (1998). Although the Kelly criterion does not employ a utility function, as pointed out by the author himself, a number of economists have adopted the point of view of utility theory to evaluate it (Latané 1959, Samuelson 1971, Levy 1973, Markowitz 1976). Various modifications, such as fractional Kelly strategies (MacLean et al. 1992) and controlled drawdowns (Grossman and Zhou 1993), have been proposed to increase the security of the resulting portfolios. A detailed review of the advantages, drawbacks and modifications of the Kelly criterion is presented in MacLean and Ziemba (2006). For an exposition of the Kelly approach in the context of information theory see Cover and Thomas (2006).

In this paper, we shall discuss the original Kelly strategy in the framework of a simple stochastic model and without assuming the existence of a utility function. We will present approximate analytical results for optimal portfolios in various situations, as well as numerical solutions and computer simulations. We will show that, in the limit of small returns and volatilities, when there is no risk-free asset, the Kelly-optimal portfolio lies on the EF. Furthermore, we shall analytically study the conditions under which diversification is no longer profitable and the optimal portfolio ‘condenses’ on a few assets. Such condensation (or underdiversification) is said to be typical for the Kelly portfolio (MacLean and Ziemba 2006) and
here we examine it in various model scenarios. Finally, we will consider the fluctuations of the logarithm of wealth as a measure of risk, and compare it with the classic M-V picture.

This paper is organized as follows. After introducing a multiplicative stochastic model for the dynamics of assets’ prices, we briefly list the main results of the Markowitz Mean-Variance approach. In section 2, we apply Kelly’s method to our model, analysing the case of one, two and many risky assets, both with and without additional constraints. Finally, a combination of the Markowitz EF with the Kelly strategy is investigated. In the appendices we explain the approximations used in this paper as well as a generalization of the model to the case of correlated asset prices.

1.1. A simple model

We shall study the portfolio optimization on a very simple model which leads to lognormally distributed returns. Consider \( N \) assets, whose prices \( p_i(t) \) (\( i = 1, \ldots, N \)) undergo uncorrelated multiplicative random walks:

\[
p_i(t) = p_i(t-1) e^{\eta_i(t)}. \tag{1}
\]

Here the random numbers \( \eta_i(t) \) are drawn from Gaussian density distributions of fixed mean \( m_i \) and variance \( D_i \), and are independent of their value at previous time steps. This model can be easily generalized to the case of non-Gaussian densities and correlated price variations, as discussed in appendix B; the influence of correlations on the Kelly portfolio is investigated in Medo et al. (2009).

We assume that the investor knows exact values of the parameters \( m_i, D_i \) for the effects of wrong parameter estimates and the details of the Bayesian parameter-learning process, see MacLean et al. (2004), MacLean and Ziemba (2006) and Medo et al. (2008). We further assume the existence of a risk-free asset paying zero interest rate.

For the sake of simplicity, we do not include dividends, transaction costs and taxes in the model. Hence, the return of asset \( i \) is \( R_i(t) := [p_i(t) - p_i(t-1)]/p_i(t-1) = e^{\eta_i(t)} - 1 \), which is lognormally distributed with the average \( \mu_i := E(R_i) = \exp[m_i + D_i/2] - 1 \) and the volatility \( \sigma_i^2 := \exp[(R_i - \mu_i)^2] = (\exp[D_i] - 1)\exp[2m_i + D_i] \).

With \( E \) we denote averages over noise \( \eta_1(t), \ldots, \eta_N(t) \).

A portfolio is determined by the fractions \( q_i \) of the total capital invested in each one of \( N \) available assets; the rest is kept in the risk-free asset. Since \( m_i \) and \( D_i \) are fixed, both the Kelly strategy and the EF use one-time-step optimization and the basic quantity is the wealth after one time step \( W_1 \). If we set the initial wealth to 1, \( W_1 \) has the form

\[
W_1 = 1 + \sum_{i=1}^{N} q_i R_i = 1 + R_P, \tag{2}
\]

where \( R_P := \sum_{i=1}^{N} q_i R_i \) is the portfolio return. To simplify the computation we assume infinite divisibility of the investment. Thus, the investment fractions \( q_i \) are real numbers and do not need to be rounded.

In the portfolio optimization, some common constraints are often imposed and can as well be applied in the present context. For instance, the non-negativity of the investment fractions \( q_i \geq 0 \) forbids short positions. The condition \( \sum_{i=1}^{N} q_i = 1 \) indicates the absence of a riskless asset and \( \sum_{i=1}^{N} q_i \leq 1 \) does not allow the investor to borrow money.

1.2. The Mean-Variance approach

The unconstrained maximization of the expected capital gain results in the investment of the entire wealth on the asset with the highest expected return; this strategy is sometimes referred to as risk neutral. If the investor has a strong aversion to risk, on the other hand, one might be tempted simply to minimize the portfolio variance \( \sigma_P^2 = \sum_{i=0}^{N} q_i^2 \sigma_i^2 \). This leads to investing the entire capital on the risk-free asset with no chance to benefit from asset price movements. The Mean-Variance (MV) approach is much more reasonable as it allows to one compromise between the gain and the risk. Here we recount basic results of this standard tool.

With the desired expected return fixed at \( E(R_P) = \mu_P \), the constrained minimization of the portfolio variance \( \sigma_P^2 \) is performed using the Lagrange function \( \mathcal{L} = E(R_P^2) + \gamma (E(R_P) - \mu_P) \) with a Lagrange multiplier \( \gamma \). The resulting optimal fractions are

\[
\hat{q}_i = \mu_P \frac{\mu_i}{\sigma_P^2}, \quad \text{where} \quad C_k = \sum_{j=1}^{N} \frac{\mu_j^2}{\sigma_j^2}. \tag{3}
\]

For \( \mu_P = 0 \), \( \hat{q}_i = 0 \) for all assets. As we increase \( \mu_P \), all optimal fractions \( \hat{q}_i \) grow in a uniform way and their ratios are preserved. At some value \( \mu_P^* \) we reach \( \sum \hat{q}_i = 1 \), which means we are investing the entire capital. Any further increase would require borrowing money, with equation (3) remaining valid as long as the borrowing rate equals the lending rate (both set to zero here). The relation between \( \sigma_P \) and \( \mu_P \) is

\[
\sigma_P = \mu_P / \sqrt{C_2}. \tag{4}
\]

This equation is often referred to as Capital Market Line (CML).

If there is no risk-free asset in the market, one has to introduce the additional constraint \( \sum_{i=1}^{N} \hat{q}_i = 1 \). It follows that

\[
\sigma_P^2 = \frac{C_0 \mu_P^2 - 2C_1 \mu_P + C_2}{C_0 C_2 - C_1^2}. \tag{5}
\]

The functional relation between the optimized \( \sigma_P \) and \( \mu_P \) is called the Efficient Frontier (EF). Since there is only one point on the CML where \( \sum \hat{q}_i = 1 \), this line is tangent to the EF. The results of this section are plotted in figure 1 for a particular choice of three available assets.

2. The Kelly portfolio

When the investor’s capital follows a multiplicative process, after many time steps its expected value is strongly influenced by rare events and in consequence it is not reasonable to form a portfolio by simply
Reduced in the appendix we shall work out approximative analytically. With the help of the approximations introduction for Kelly-optimal portfolio is $v$ (1956). Thus the key quantity in the construction of a tangent point of the two is the Market Portfolio (MP). The thick part of EF marks the region where all investment fractions are positive.

maximizing $E(W(i))$. The Mean-Variance approach tries to solve this problem in a straightforward, yet criticisable, way. We support here the idea that an efficient investment strategy can be found by maximizing the investment growth rate in the long run, which is, under the assumption of fixed asset properties, equivalent to maximizing the logarithm of the wealth $W_i$ after one time step (Kelly 1956). Thus the key quantity in the construction of a Kelly-optimal portfolio is $v := E(ln W_i)$, the average exponential growth rate of the wealth. Recall that the quantity $ln W_i$ is not a logarithmic utility function.

In Maslov and Zhang (1998), $v$ is optimized in a similar context and the authors claim that their procedure corresponds to maximizing the median of the distribution of returns. They consider short time intervals and thus small assets returns. Assuming $R_p \ll 1$ (very small portfolio return), they use the approximation $ln(1 + R_P) \approx R_P - R_P^2/2$ of the logarithm in the expression for $v$ before maximizing it. However, while such an expansion is only justified for $R_P \ll 1$, the maximum of the resulting function is at $R_P = 1$, contradicting the hypothesis. We will develop a different approximation in the following.

First, the unconstrained maximization of $v$ is achieved by solving the set of equations $\partial v / \partial q_i = 0$ ($i = 1, \ldots, N$). After exchanging the order of the derivative and the average, we obtain the condition

$$E \left( \frac{R_i}{1 + \sum_j q_j R_j} \right) = 0 \quad (i = 1, \ldots, N).$$

(6)

In our case, $R_i$ has a lognormal distribution and, to our knowledge, this set of equations cannot be solved analytically. With the help of the approximations introduced in the appendix we shall work out approximative solutions for some particular cases. We emphasize an important restriction which applies to all solutions of equation (6). Since returns $R_i$ lie in the range $(-1, \infty)$, when $\sum_i q_i > 1$ or when there is an investment fraction $q_i < 0$, there is a non-zero probability that $W_i$ is negative and hence $v = E(ln W_i)$ is not well defined. Since Kelly’s approach focuses on the long run, it requires strictly zero probability of getting bankrupted in one turn. As a consequence, for lognormally distributed returns any Kelly strategy must obey $q_i \geq 0$ and $\sum_i q_i \leq 1$, i.e. both short selling and borrowing must be avoided.

2.1. One risky asset

Let us begin the reasoning with the case of one risky asset. We want to find the optimal investment fraction $q$ of the available wealth. The remaining fraction $1 - q$ we keep in cash at the risk-free interest rate which, without loss of generality, is set to zero. This problem is described by equation (6) in one dimension; even this simplest case has no analytical solution. Nevertheless, for a given $D$, one can ask what is the value $m_<$ for which it becomes profitable to invest a positive fraction of the investor’s capital in the risky asset. This can be found by imposing $q = 0$ in equation (6), yielding $m_<= -D/2$. Similarly, the value $m_>$ for which it becomes profitable to invest the entire capital can be found by imposing $q = 1$, yielding $m_> = D/2$.

We shall look for approximate solutions that are valid for small values of $D$, which is the case treated in appendix A. Using approximation equation (A2) in equation (6) gives

$$\frac{e^m - 1}{1 - q + q e^m} + \frac{D}{2} \frac{e^m (1 - q - q e^m)}{(1 - q + q e^m)^3} = 0.$$  

With respect to $q$, this is merely a quadratic equation. Since the solution is rather long, we first simplify the equation using $m, D \ll 1$ as in equation (A3), leading to the result

$$\hat{q} = \frac{1}{2} + \frac{m}{D}.  

(7)$$

Since borrowing and short selling are forbidden, $\hat{q} = 0$ for $m < -D/2$ and $\hat{q} = 1$ for $m > D/2$. When asset prices undergo a multiplicative random walk with lognormal returns, both $m$ and $D$ scale linearly with the time scale and hence $\hat{q}$ does not depend on the length of the time step. Notice also that substituting $m = \pm D/2$ gives $\hat{q} = 0$ and $\hat{q} = 1$, in agreement with the bounds we found before by exact computation. The first-order correction to equation (7) is $m(4m^2 - D^2)/4D^2$ which is, for $m \in [-D/2, D/2]$, of order $O(m)$. The validity of the presented approximations can be easily tested by a straightforward numerical maximization of $E(ln W_i)$. As can be seen in figure 2, the numerical results are well approximated by analytical formula (7) even for $D = 1$.

Notice that, for $m, D \ll 1$, one can approximate $\mu \approx m + D/2$ and $\sigma^2 \approx D$, which makes the optimal portfolio fraction derived above equal to $\hat{q} = \mu/ (\mu^2 + \sigma^2)$ obtained in Maslov and Zhang (1998).
However, if we check the accuracy of $\hat{q}_i$, we find a relative error up to 3% for $D = 0.01$, and for $D = 0.25$ we are already far out of the applicability range with an error around 50%. Also, equation (7) is for $m, D \ll 1$ identical to the classical Merton result (Merton 1969) which is derived under the assumption of continuous-time, non-zero consumption of the wealth, and a logarithmic utility function. In Browne and Whitt (1996) and Platen and Heath (2006), the result $\hat{q}_i = \frac{1}{2} + m_i/D_i$ is derived for the continuous time limit of our model: $m_i = 0$, $m_i/D_i = \text{const.}$

### 2.2. Constrained optimization

The optimal portfolio fractions $q_i$, can be derived from equation (6) also for $N > 1$. Using the same approximations as in the single asset case, we obtain the general formula $\hat{q}_i = 1/2 + m_i/D_i$ for $i = 1, \ldots, N$. In our case, Kelly’s approach forbids short selling and hence the assets with $\hat{q}_i < 0$ do not enter the optimal portfolio. Since borrowing is also forbidden, if $\sum_{i=1}^{N} \hat{q}_i > 1$, we have to introduce the additional constraint $\sum_{i=1}^{N} q_i = 1$. This can be done by use of the Lagrange function $L(q, \lambda) = \gamma + \gamma (\sum_{i=1}^{N} q_i - 1)$ where $q$ is the vector of investment fractions. The optimal portfolio is then the solution of the set of equations

$$\sum_{j=1}^{N} q_j = 1, \quad E\left(\frac{R_i}{1 + \sum_{j=1}^{N} q_j R_i}\right) + \lambda = 0 \quad (i = 1, \ldots, N),$$

where $R_i = e^{\mu_i} - 1$. Using the same approximations again, one obtains the general result

$$\hat{q}_i = \frac{1}{2} + \frac{m_i + \lambda}{D_i}.$$  

The Lagrange multiplier $\lambda$ is fixed by the condition $\sum_{i=1}^{N} \hat{q}_i = 1$. It can occur that even a profitable asset with $m_i > -D_i/2$ has a negative optimal investment fraction. Since in our case the Kelly approach forbids short selling, this asset has to be eliminated from the optimization process. In consequence, under some conditions, only a few assets are included in the resulting optimal portfolio. This phenomenon, which we call portfolio condensation, we study more closely in sections 2.3 and 2.4. An alternative approach to the constrained Kelly-optimal portfolio is provided by the Kuhn–Tucker equations (see Cover and Thomas 2006, chap. 16) which, however, can be shown to be equivalent to equation (8).

Now we can establish an important link to Markowitz’s approach: in the limit $\mu_i, \sigma_i \to 0$ the Kelly portfolio lies on the constrained EF (no short selling allowed). We shall prove this statement in the following. When all the assets have small $\mu_i$ and $\sigma_i$, in equations (3) and (5) we can approximate $\mu_i \approx m_i + D_i/2$ and $\sigma_i^2 \approx D_i$, leading to the approximative relation for the EM

$$\sigma_i^2 = \frac{\tilde{C}_0 \mu_i^2 - 2 \tilde{C}_1 \mu_i + \tilde{C}_2}{\tilde{C}_0 C_2 - \tilde{C}_1^2}, \quad \text{where} \, \tilde{C}_k = \sum_{i=1}^{N} (m_i + D_i/2)^k.$$  

(10)

For the Kelly portfolio we need to work out a similar approximation. Using the condition $\sum \hat{q}_i = 1$, for $\gamma$ in equation (9) we obtain $\gamma = (1 - \tilde{C}_1)/\tilde{C}_0$. In the relations $\mu_p = \sum \hat{q}_i \mu_i$ and $\sigma_p^2 = \sum \hat{q}_i^2 \sigma_i^2$ we use the approximations for $\mu_i, \sigma_i$ introduced above. After substituting $\hat{q}_i$ from equation (9), for the Kelly optimal portfolio we get

$$\mu_K = \frac{\tilde{C}_0 C_2 - \tilde{C}_1^2 + 1}{\tilde{C}_0}, \quad \sigma_K^2 = \frac{\tilde{C}_0 C_2 - \tilde{C}_1^2 + 1}{\tilde{C}_0}.$$  

(11)

Both in equations (10) and (11) we consider only the assets that have positive investment fractions. Now it is only a question of simple algebra to show that $\mu_K$ and $\sigma_K$ given by equation (11) fulfil equation (10), which completes the proof. Similar, yet weaker, results can be found in the literature. For instance, Markowitz (1976) states that ‘on the EF there is a point which approximately maximizes $E(ln W_t)$’.

Obtained results are illustrated in figure 3, where we plot the EF, the constrained EF, and the Kelly portfolio for the same three assets as in figure 1. While the original EF is not bounded (for any $\mu_p$, there exists an appropriate $\sigma_p$), the constrained EF starts at the point corresponding to the full investment in the least profitable asset and ends at the point corresponding to the most profitable asset. The two lines coincide on a wide range of $\mu_p$. In agreement with the previous paragraph, the Kelly portfolio lies close to the constrained EF.

### 2.3. Condensation in the two-asset case

To illustrate the condensation phenomenon we focus on a simple case here: two risky assets plus a risk-free one, borrowing and short selling forbidden. As we have already seen, without constraints, $\hat{q}_i = 1/2 + m_i/D_i$. Therefore, when $m_i < -D_i/2$, $\hat{q}_i$ is negative and, due to forbidden short selling, asset $i$ drops out of the optimal portfolio. In figure 4 this threshold is shown for $i = 1, 2$ by

Figure 2. The optimal portfolio fraction $\hat{q}_i$: a comparison of the analytical result (equation 7) with a numerical maximization of $E(ln W_t)$.
The solid line constrained optimization has to be used. Figure 3. The Efficient Frontier (EF, thin solid line), EF without short selling (bold line), and the Kelly portfolio (solid square) in a particular case of three assets (asset parameters as in figure 1).

Figure 4. The phase diagram of the two-asset system with \( D_1 = 0.1 \) and \( D_2 = 0.2 \). In region A the investor is advised to use only the risk-free asset. In regions B, B2 and C the optimal investment is still partially in the risk-free asset. In regions D1, D2, E, F1 and F2 one should invest everything in the risky assets. While in regions C and E the investment is divided between the two assets, in shaded regions F1 and F2 a non-trivial condensation arises: one is advised to invest all wealth in one asset although the other one is also profitable.

The condensation to one of the two assets arises when the optimal fractions \( (\hat{q}_1, \hat{q}_2) \) are either \((1,0)\) or \((0,1)\); we can find the values \( m_1^* \) and \( m_2^* \) when this happens. By eliminating \( \gamma \) from equation (8) and substituting \( q_1 = 1 \) and \( q_2 = 0 \) we obtain the condition for the condensation on asset 1: \( E[(e^{r_1} - 1)/e^{r_1}] = E[(e^{r_2} - 1)/e^{r_2}] \). This can be solved analytically, yielding

\[
m_1^* = m_2 + \frac{D_1 + D_2}{2}.
\]

This equation holds with interchanged indices for the condensation on asset 2, thus \( m_2^* = m_2 - (D_1 + D_2)/2 \). Finally, for \( m_1^* < m_1 < m_2^* \) the optimal portfolio contains both assets. The crossover values \( m_1^* \) and \( m_2^* \) are shown in figure 4 as dotted lines. They delimit the region where the portfolio condenses to only one of two profitable assets. A complete ‘phase diagram’ of the optimal investment in the two-asset case is presented in figure 4 for a particular choice of the asset variances. Interestingly, growth-rate optimizing strategies have their importance also in evolutionary biology (Yoshimura and Jansen 1996) where a similar condensation phenomenon has been observed when studying evolution in an uncertain environment (Bergstrom and Lachmann 2004).

2.4. Many assets with equal volatility

We investigate here the case of an arbitrary large number \( N \) of available assets where Kelly’s approach, which forbids borrowing and short selling, gives rise to a portfolio condensation. While the optimal portfolio fractions are given by equation (9), to find which assets are included in the optimal portfolio is a hard combinatorial task. To obtain analytical results, we simplify the problem by assuming that the variances of all assets are equal, \( D_i = D \quad (i = 1, \ldots, N) \). The number of assets contained in the optimal portfolio is labelled as \( M \) and the assets are sorted in order of decreasing \( m_i \) (\( m_1 > m_2 > \cdots > m_N \)).

If the unconstrained optimization does not violate forbidden borrowing, then the profitability of an asset (i.e. \( m_i > -D/2 \)) is the only criterion for including it in the optimal portfolio. When the constrained optimization is necessary, the optimal portfolio is formed by starting from the most profitable asset \( m_1 \), and adding the others one by one until the last added asset has a non-positive optimal fraction \( q_{M+1} \leq 0 \). Summing equation (9) from 1 to \( M \), we can write \( \gamma (M) = D(M^{-1} - 1/2) - 1 \sum_{i=1}^{M} m_i \). For a given realization of \( \{m_i\} \), we can obtain the resulting portfolio size by finding the largest \( M \) that satisfies \( q_M > 0 \), which leads to

\[
m_M + \frac{D}{M} \geq \frac{1}{M} \sum_{i=1}^{M} m_i.
\]

This relation tells us how many assets we should invest on, once their expected growths and volatility are known. Notice that for \( M = 2 \) and \( D_1 = D_2 = D \), this result is consistent with that of equation (12) where a special case of the condensation on two assets is described.
Let us follow now a statistical approach. If all \( m_i \) are drawn from a given distribution \( f(m) \), the value of \( M \) depends on the current realization. The characteristic behaviour of the system can be found by taking the average over all possible realizations and replacing \( m_i \) by \( \bar{m}_i \). The resulting typical portfolio size \( M_T \) captures this behaviour and depends on the distribution \( f(m) \) and on the number of available assets \( N \).

### 2.4.1 Uniform distribution of \( m \)

Let us first analyse the case of a uniform distribution of \( m_i \) within the range \( [a, b] \). First we assume that all assets are profitable, i.e. \( a + D/2 > 0 \). For the case when \( m_i \) are sorted in decreasing order, one can show \( \bar{m}_i = b - (b - a)i/(N + 1) \). Since \( \bar{m}_i \) declines with \( i \) linearly, according to equation (9) so does \( \bar{q}_i \). Substituting \( \bar{m}_i \) for \( m_i \) in equation (13) and replacing ‘\( > \)’ with ‘\( = \)’, we can estimate the typical number of assets in the optimal portfolio \( M_T \). Assuming \( M_T \gg 1 \), the solution has the simple form \( M_T = \sqrt{\pi ND/(b - a)} \).

We are now able to generalize this result to the case where not all assets are profitable, i.e. \( m_i + D/2 < 0 \) for some \( i \)'s. In the extreme case \( b + D/2 < 0 \) and all assets are unprofitable, leading to \( M = M_T = 0 \). The opposite extreme is realized for \( m_{i+1} + D/2 > 0 \) which falls in the previously treated case because the number of profitable assets is larger than \( M_T \). In the intermediate region, only the assets with \( m_i > -D/2 \) are profitable and enter the optimal portfolio. On average, they are \( N(b + D/2)/(b - a) \). All together we have the formula

\[
M_T = \begin{cases} 
0 & (b + D/2 < 0), \\
N(b + D/2)/(b - a) & (b + D/2 > 0, \ m_{M_T} + D/2 < 0), \\
\sqrt{2ND/(b - a)} & (m_{M_T} + D/2 > 0).
\end{cases}
\]

(14)

In figure 5, left, an illustration of a particular system \((a = x - L, \ b = x + L, \ x = -0.05)\), motivated by A. Capocci, private communication) is shown. We plot \( M_T \) and \( \mu_P \) as functions of \( L \). When \( L \) is small, all available assets are unprofitable and the optimal strategy is to keep the entire capital at the risk-free rate. As soon as the first profitable assets are added to the system, the optimal portfolio includes all of them, until it saturates at the value \( \sqrt{ND}/L \) (in equation 14 we substitute \( b - a = 2L \)). A further increase of \( L \) widens the distribution of \( m \) and enlarges the gaps between profitable assets. It becomes, as a consequence, more rewarding to drop the worse ones and \( M_T \) decreases. The analytical solution, displayed in figure 5 as a solid line, is in good agreement with the numerical results (shown as symbols). Although no single-asset portfolio arises in this case, the relative portfolio size is \( M_T/N \approx 1/\sqrt{N} \) and hence, in the large \( N \) limit, the optimal portfolio condenses to a small fraction of all available assets.

A more flexible measure of the level of condensation is the inverse participation ratio, defined as \( R = 1/\sum_{i=1}^N q_i^2 \). It estimates the effective number of assets in the portfolio: when all investment fractions are equal, \( R = N \), while, when one asset covers 99% of the portfolio, \( R \approx 1 \). Concerning the typical case, using equation (9) we can write \( q_i = A - B_i \), \( B_i = (b - a)/[N(D/2)] \), the detailed form of \( A \) is not needed for the solution. We assume that the number of profitable assets is larger than the typical size of the optimal portfolio \( M_T \). Consequently, passing from \( i = 1 \) to \( i = M_T \), \( q_i \) decreases linearly to zero and we can use the identity \( \sum_{i=1}^{M_T}(A - B_i)^2 = \sum_{i=1}^{M_T}B_i^2 \) to obtain

\[
R = \left[ B^2M_T(M_T + 1)(2M_T + 1)/9 \right]^{-1} \approx \left[ B^2M_T^3/3 \right]^{-1} \approx 1/4 M_T.
\]

(15)

In the last step we used equation (14) for the typical size of the condensed optimal portfolio. We see that the

Figure 5. Left: In the case with \( m_i \) uniformly distributed in \([x - L, x + L]\) we plot the size of the optimal portfolio \( M_T \) (the solid line represents the analytical result of equation (14); symbols are numerical results averaged over 10000 repetitions). With the dashed line, the portfolio return \( \mu_P \) (measured in per cent) is shown. The parameters are \( N = 1000, D = 0.01, x = -0.05 \). Right: In the case of \( N \) assets with \( D = 0.01 \) and \( m_i \) uniformly distributed in \([0, 0.1]\), we plot the average size of the optimal portfolio \( M_T \) and the inverse participation ratio \( R \). Solid lines are the analytical solutions reported in equations (14) and (15); symbols stand for numerical results.
uniform distribution of \( m_1 \) leads to an inverse participation ratio proportional to the number of assets in the portfolio. In the right-hand side graph of figure 5, equation (15) is shown to match the numerical solution (based on equation (13)) for various numbers of available assets.

2.4.2. Power-law distribution of \( m \). Now we treat the case of a distribution \( f(m) \) that has a power-law tail: \( f(m) = Cm^{-\alpha - 1} \) for \( m > m_{\text{min}} \). As long as \( M \ll N \), the properties of the assets included in the optimal portfolio are driven by the tail of \( f(m) \). In consequence, the detailed form of \( f(m) \) for \( m < m_{\text{min}} \) is not important here. We assume that only a fraction \( r \) of all assets falls in the region \( m > m_{\text{min}} \).

Instead of seeking the typical portfolio size \( M \), we shall limit ourselves to finding the conditions when a condensation on one asset arises. With this aim in mind, we put \( M = 2 \) in equation (13), obtaining the equation \( m_1 - m_2 = D \). When \( m_1 - m_2 > D \), only asset 1 is included in the optimal portfolio. By replacing \( m_1 \) and \( m_2 \) with their medians \( \tilde{m}_1 \) and \( \tilde{m}_2 \), one obtains an approximate condition for a system where such a condensation typically exists. Using order statistics (David and Nagaraja 2003) we find the following expressions for the medians: \( \tilde{m}_1 = m_{\text{min}}(N/r/\ln 2)^{1/\alpha} \), \( \tilde{m}_2 = m_{\text{min}}(N/1.68)^{1/\alpha} \). The equation \( \tilde{m}_1 - \tilde{m}_2 = D \) thus achieved can be solved numerically with respect to \( \alpha \). In this way we find the value \( \alpha_1 \) below which the optimal portfolio typically contains only the most profitable asset. In figure 6 we plot the result as a function of \( D \). For comparison, the outcomes from a purely numerical investigation of the equation \( P(m_1 - m_2 > D) = 0.5 \) are also shown as filled circles. Our approximate condition has the same qualitative behaviour as the simulation, showing that the use of the median gives us a good notion of the optimal portfolio behaviour.

3. Efficient frontiers

Markowitz’s efficient frontier is the line where efficient portfolios are supposed to lie in the Mean-Variance picture. Here we would like to follow the same procedure, using typical instead of average quantities. To capture a typical case, we replace the portfolio return \( R_P \) by \( \ln W_1 \) in all averages of section 1.2. According to the formula \( E[(x - E(x))^2] = E(x^2) - E(x)^2 \) we can minimize \( E[\ln W_1^2] - E[\ln W_1]^2 \) instead of \( E[\ln W_1^2 - E(\ln W_1)]^2 \). With the constraints \( E[\ln W_1] = v_P \) and \( \sum_{i=1}^{N} q_i = 1 \), the Lagrange function has the form

\[
\mathcal{L} = E[\ln W_1^2] + \gamma_1 (E[\ln W_1] - v_P) + \gamma_2 \left( \sum_{i=1}^{N} q_i - 1 \right).
\]

(16)

Its analytical maximization leads to complicated equations and thus it is convenient to investigate the system numerically; we do so in the particular case of three assets used in figure 1. Due to the two constraints there is effectively only one degree of freedom for the minimization of \( E[\ln W_1^2] \) and the numerical procedure may be straightforward.

For the resulting portfolios we can compute expected returns and variances which allows us to add this Logarithmic Efficient Frontier (LEF) to the \( \sigma_P - \mu_P \) plane depicted in figure 1. The result is shown in figure 7, where the solid line is again Markowitz’s EF. Solid circles correspond to the three individual assets. The dashed line represents the LEF (obtained by the numerical optimization described above) and the thick grey curve is the region where both EF and LEF consist only of positive portfolio fractions. The solid square represents the Kelly portfolio as follows from equation (9) (again, short selling and

![Figure 7. Comparison of two efficient frontiers. The solid line is the classic EF given by equation (5). The dashed line is obtained by fixing \( E[\ln W_1] \) and by numerically minimizing fluctuations of \( \ln W_1 \) around this value. This we call the Logarithmic Efficient Frontier (LEF), its portion with positive \( q_i \) values is highlighted in thick gray. The small filled circles represent the three individual assets that compose the system. The filled square is the Kelly-optimal portfolio (no borrowing, no short selling).](http://doc.rero.ch)
borrowing are forbidden). We see that the EF and the LEF are close to each other and thus from a practical point of view they do not differ.

Finally, let us discuss a useful simplification which allows us, in some cases, to reduce the time-consuming numerical computations. By differentiating equation (16) we obtain the condition for the optimal portfolio fractions

$$E\left(\frac{2\ln W_i}{W_i} R_i\right) + \gamma_1 E\left(\frac{R_i}{W_i}\right) + \gamma_2 = 0 \quad (i = 1, \ldots, N).$$

(17)

When the parameters of all assets fulfil the condition \(m_i, D_i \ll 1\), we can use the approximations for \(E(R_i/W_i)\) introduced in appendix A. The first term can be evaluated more precisely using \(\ln W_i = \ln(1 + R_p) \approx R_p\).

Hence \(E(R_i/W_i) \approx q_i E(R_i^2) + \sum_{j \neq i} q_j E(R_i)E(R_j)\), where \(R_i = e^{R_i} - 1\) is the return of asset \(i\). Furthermore, for \(m_i, D_i \ll 1\) we have \(E(R_i) \approx m_i + D_i/2\) and \(E(R_i^2) \approx D_i\). As a result we obtain the equations

$$2q_i D_i + (m_i + D_i/2) \sum_{j \neq i} q_j (m_j + D_j/2) + \gamma_1 \left[ m_i + D_i/2 (1 - 2q_i) \right] + \gamma_2 = 0,$$

(18)

where \(i = 1, \ldots, N\) and the values of \(\gamma_1\) and \(\gamma_2\) are fixed by the constraints \(\sum_{i=1}^{N} q_i (m_i + D_i/2) = v_p\), \(\sum_{i=1}^{N} q_i = 1\). This set of \(N + 2\) nonlinear equations allows us to find the LEF approximately. In comparison with a straightforward numerical maximization of equation (16) (involving numerical integration of \(E(\ln W_i)\) and \(E([\ln W_i]^2)\)), a substantial saving of computational costs is achieved.

4. Concluding remarks

In this work we investigated the Kelly optimization strategy in the framework of a simple stochastic model for asset prices. We derived a highly accurate approximate analytical formula for the optimal portfolio fractions. We proved that in the limit of small returns and volatilities of the assets, the constrained Kelly-optimal portfolio lies on the EF. Based on the obtained analytical results, we proposed a simple algorithm for the construction of the optimal portfolio in the constrained case. We showed that, since in the investigated case of lognormal returns Kelly’s approach forbids short positions and borrowing, only a part of the available assets is included in the optimal portfolio. In some cases the size of the optimal portfolio is much smaller than the number of available assets – we say that a portfolio condensation arises. In particular, when the distribution of the mean asset returns is wide, there is a high probability that only the most profitable asset is included in the Kelly-optimal portfolio.

The Mean-Variance analysis is a well-established approach to the portfolio optimization. We modified this method by replacing the averages \(E(W_i)\) and \(E(W_i^2)\) with the logarithm-related quantities \(E(\ln W_i)\) and \(E([\ln W_i]^2)\). These are less affected by rare events and allow one to capture the typical behaviour of the system. As a matter of fact, the difference between the traditional M-V approach and the modification proposed here is very small and does not justify the additional complexity thus induced.

Acknowledgements

We acknowledge partial support from the Swiss National Science Foundation (Project 205120-113842) as well as from STIPOCO (the European exchange program). We appreciate early collaboration with Dr Andrea Capocci in this research, stimulating remarks from Damien Challet in late stages of preparation of the paper, and helpful comments from our anonymous reviewers.

**Appendix A: Main approximations**

Our aim is to approximate expressions of the type \( E(g(\eta)) \), where \( \eta \) follows a normal distribution \( f(\eta) \) with the mean \( m \) and the variance \( D \). For small values of \( D \), this distribution is sharply peaked and an approximate solution can be found expanding \( g(\eta) \) around this \( m \). This expansion has the following effective form:

\[
  g(\eta) \approx g(m) + \frac{1}{2} (\eta - m)^2 g^{(2)}(m) + \frac{1}{24} (\eta - m)^4 g^{(4)}(x)
\]

(A1)

for some \( x \in [m, \eta] \). Here we dropped the terms proportional to \( (\eta - m)^2 \) with an odd exponent \( k \), for they vanish after the averaging. If we take only the first two terms into account, we obtain

\[
  E(g(\eta)) = \int_{-\infty}^{\infty} g(\eta)f(\eta)d\eta \approx g(m) + \frac{D}{2} g^{(2)}(m).
\]

(A2)

This approximation is valid when the following term of the Taylor series brings a negligible contribution \( \Delta \). We can estimate it in the following way (\( \forall \in [m, \eta] \)):

\[
  \Delta = \int_{-\infty}^{\infty} \frac{(\eta - m)^4}{24} g^{(4)}(x)f(\eta)d\eta \lesssim \int_{-\infty}^{\infty} \frac{(\eta - m)^4}{24} Mf(\eta)d\eta = \frac{MD^2}{8}.
\]

Here by \( M \) we label the maximum of \( |g^{(4)}(\eta)| \) in the region \( \chi \) where \( f(\eta) \) differs from zero considerably, e.g. \( \chi = [m - 2D, m + 2D] \). Since \( g(x) \) has no singular points in a wide neighbourhood of \( m \), its fourth derivative is a bounded and well-behaved function. Thus \( M \) is finite and \( \Delta \) vanishes when \( D \) is small.

In particular, in this work we deal with functions of the form \( g(\eta) = (e^{\eta} - 1)/(1 + e^{\eta} - 1) \). If we use equation (A2) with this \( g(\eta) \), approximate \( 1 + g(e^{\eta} - 1) \) in the resulting denominators by \( 1, e^{\eta} \) by \( 1, e^{\eta} - 1 \) by \( m \), we are left with

\[
  E(g(\eta)) \approx m + D(1 - 2q)/2.
\]

(A3)

We widely use approximations of this kind to obtain the leading terms for the optimal portfolio fractions in this paper.

**Appendix B: Procedure for correlated asset prices**

So far we have considered uncorrelated asset prices, undergoing the geometric Brownian motion of equation (1). Obviously, this is an idealized model and real asset prices exhibit various kinds of correlations. In order to treat correlated prices we employ the covariance matrix \( S \) to characterize the second moment of the stochastic terms \( E((\eta_i - m_i)(\eta_j - m_j)) = S_{ij} \). The uncorrelated case can be recovered with the substitution \( S_{ij} = \delta_{ij}D_i \).

Again, we would like to find an approximation of the term \( E(g(\eta)) = \int g(\eta)f(\eta)d\eta \). Here \( f(\eta) \) is the probability distribution of \( \eta \) and \( g(\eta) \) is the function of interest. Notice that the correlations impose the use of vector forms for all the quantities of interest. The Taylor expansion of \( g(q) \) around \( m \), equation (A1) in the uncorrelated case, takes the form

\[
  g(q) = g(m) + \nabla g(m))(q-m) + \frac{1}{2} (q-m)^T \nabla^2 g(m)(q-m) + \cdots.
\]

Here \( \nabla g(m) \) is the matrix of second derivatives of the function \( g(q) \), calculated at the point \( q = m \). Now we can proceed in the same way as before:

\[
  E(g(\eta)) \approx g(m) \int f(\eta)d\eta + \sum_{i=1}^{N} \delta_i g(m) \int (\eta_i - m_i)f(\eta)d\eta
\]

\[
  + \frac{1}{2} \sum_{i,j=1}^{N} S_{ij} V_{ij} \int f(\eta)d\eta
\]

\[
  = g(m) + \frac{1}{2} \sum_{i,j=1}^{N} S_{ij} V_{ij} = g(m) + \frac{1}{2} \text{Tr}(SV).
\]

In the last line we used the symmetry of \( S \). For given \( g(q) \), \( m \) and \( S \), we can now solve the equation \( E(g(\eta)) = 0 \).

In particular, these approximations can be cast into equation (6), which can then be treated as in the uncorrelated case.
