ABSTRACT

Flavonoids represent a class of secondary metabolites with diverse functions in plants including UV protection, pathogen defence, and interspecies communication. They are also known as modulators of signalling processes in plant and animal systems and therefore are considered to have beneficial effects as nutraceuticals. The rol1-2 (repressor of lrx1) mutation of Arabidopsis thaliana induces aberrant accumulation of flavonols and a cell-growth phenotype in the shoot. The hyponastic cotyledons, aberrant shape of pavement cells, and deformed trichomes in rol1-2 mutants are suppressed by blocking flavonoid biosynthesis, suggesting that the altered flavonol accumulation in these plants induces the shoot phenotype. Indeed, the identification of several tt (transparent testa), myb, and ffs1 (flavonol synthase1) alleles in a rol1-2 suppressor screen provides genetic evidence that flavonols interfere with shoot development in rol1-2 seedlings. The increased accumulation of auxin in rol1-2 seedlings appears to be caused by a flavonol-induced modification of auxin transport. Quantification of auxin export from mesophyll protoplasts revealed that NAA but not IAA transport is affected by the rol1-2 mutation. Inhibition of flavonol biosynthesis in rol1-2 ffs1-3 restores NAA transport to wild-type levels, indicating a very specific mode of action of flavonols on the auxin transport machinery.
INTRODUCTION

Plants produce a wide variety of secondary metabolites that cover different functions. Flavonoids are synthesized via the phenylpropanoid pathway and serve as UV protectants, in pathogen defence, for plant-microorganism communication, and the regulation of reactive oxygen species (Lepiniec et al., 2006; Buer et al., 2010). A large number of flavonoids are produced by plants and flavonols represent a subgroup of flavonoids. In Arabidopsis thaliana, the flavonols quercetin, kaempferol, and isorhamnetin are glycosylated at the C3 and C7 position mainly with glucose (Glu) and rhamnose (Rha), resulting in a large number of different glycosidic forms (Veit and Pauli, 1999; Lepiniec et al., 2006). The biosynthesis of flavonoids and flavonols has been extensively characterized (Fig. 1) and a number of mutants affected in this pathway have been identified. The Arabidopsis transparent testa (tt) mutants were isolated based on the pale yellow color of the seed coat due to the absence of proanthocyanidins, a final product of flavonoid biosynthesis. A number of these lines are mutated in genes coding for enzymes active in this pathway (Koornneef et al., 1990; Shirley et al., 1995; Routaboul et al., 2006). R2R3-MYB transcription factors control the accumulation of flavonols in an additive manner by regulating gene expression of several genes and the Arabidopsis myb11 myb12 myb111 triple mutant is devoid of flavonols (Stracke et al., 2007). Flavonols are primarily synthesized from dihydroflavonols by FLAVONOL SYNTHASE (FLS) (Prescott et al., 2002, Martens et al., 2010). In Arabidopsis, of five FLS homologs, only FLS1 shows a strong and FLS3 a very moderate activity (Wisman et al., 1998; Owens et al., 2008; Preuss et al., 2009).

A function of flavonols during plant development has been demonstrated in different plant species. Blocking flavonoid biosynthesis in Petunia hybridae results in pollen and root-hair growth defects and flavonols are important for the formation of a functional pollen tube in Zea mays (Mo et al., 1992; Taylor and Grotewold, 2005). The flavonoid-less tt4 mutant of Arabidopsis (Fig. 1) shows reduced gravitropic response and is affected in the transport of the phytohormone auxin (Buer and Muday, 2004). This observation might be related to the altered cycling of the auxin efflux facilitator PIN1 in the tt4 mutant background (Peer et al., 2004). Flavonols can compete with the auxin transport inhibitor NPA for binding to proteins involved in auxin transport (Jacobs and Rubery, 1988; Noh et al., 2001; Murphy et al., 2002;
and the kaempferol overaccumulator tt7 is affected in auxin transport (Peer et al., 2004). Hence, several experiments hint at flavonols being involved in modifying auxin transport (Peer and Murphy, 2006). At this point, however, such experiments were not performed on FLS1-less Arabidopsis mutants. One of the problems is that the stable fls1 mutants available so far are not in the Columbia genetic background. Different Arabidopsis accessions show distinct developmental properties and flavonol accumulation (Routaboul et al., 2006; Juenger et al., 2010), making the combination of several mutations in different genetic backgrounds potentially difficult to interpret (Massonnet et al., 2010).

The Arabidopsis rol1-2 mutant shows a strong shoot phenotype in seedlings that seems to be under the influence of flavonols. The rol1-2 mutant is affected in the RHAMNOSE SYNTHASE RHM1. Rha is used for the biosynthesis of pectin and glycosylation of flavonols and rol1-2 mutants are affected in the pectin structure as well as the glycosylation pattern of flavonols (Diet et al., 2006; Ringli et al., 2008). While the amount of rhamnosylated flavonols is reduced in rol1-2, glucosylated flavonols are more abundant. The rol1-2 phenotype is characterized by short roots and root hairs, hyponastic cotyledons with adaxial pavement cells lacking the typical puzzle-like cell shape, and deformed trichomes on the first rosette leaves. The hyponastic cotyledons but not the pavement cell and trichome phenotype seem to be induced by the increased auxin concentration. A rol1-2 tt4 double mutant developed the rol1-2 mutant root phenotype but a wild type-like shoot where all rol1-2 shoot phenotypes were fully suppressed (Ringli et al., 2008). Hence, blocking flavonoid biosynthesis suppresses the rol1-2 shoot phenotype, indicating that flavonols accumulating in the rol1-2 mutant influence shoot development. By contrast, the effect of the rol1-2 mutation on root development seems largely independent of flavonols.

A suppressor screen was performed on the rol1-2 mutant, leading to the isolation of several new tt, myb111, and four fls1 alleles. These lines provide genetic evidence for flavonols being the inducers of the rol1-2 shoot phenotype. Localization of RHM1 and FLS1 reveal adaxial accumulation of these proteins in cotyledons which explains the asymmetric cell growth observed in rol1-2. Ectopic expression of FLS1 demonstrates that flavonols are not distributed within the plant. One function of
flavonols in rol1-2 appears to be the influence on auxin transport, as exemplified by protoplast-based auxin transport.

RESULTS

Suppression of rol1-2 by Inhibition of Early Steps of Flavonoid Biosynthesis

To characterize the role of flavonoids in the establishment of the rol1-2 mutant phenotype, modification of flavonoid biosynthesis in rol1-2 was taken as an approach. To this end, rol1-2 mutant seeds were subjected to mutagenesis with ethyl methanesulfonate (EMS) and propagated to the M2 generation (for details, see MATERIALS AND METHODS). Previous work suggests that blocking the pathway prior to flavonol biosynthesis (Fig. 1) leads to suppression of the rol1-2 shoot phenotype (Fig. 2, A-C), whereas blocking the pathway further downstream does not have this effect (Ringli et al., 2008). As proof of concept, M2 seedlings with a reduced anthocyanin accumulation, based on pale-green hypocotyls, were identified. These could be divided in two classes: i) no suppression of the rol1-2 shoot phenotype (i.e. hyponastic cotyledons; Fig. 2G) and ii) suppression of the shoot rol1-2 phenotype (i.e. epinastic cotyledons; Fig. 2H).

Mutants falling within the first class were used to sequence genes involved in flavonoid biosynthesis downstream of the branch point of flavonol biosynthesis. Among these mutants, new alleles of tt3, tt7, and tt18 were identified (Fig.1, Table I). TT3 encodes a dihydroflavonol-4-reductase and TT18 a leucoanthocyanidin dioxygenase. The respective mutants tt3 and tt18 both lack anthocyanins but accumulate the flavonols quercetin and kaempferol. TT7 encodes the flavonol 3'-hydroxylase and the tt7 mutant only accumulates the flavonol kaempferol but not quercetin and no anthocyanins. These data confirm that TT7 and hence the accumulation of quercetin or enzymes acting downstream of TT7 are dispensable for the development of the rol1-2 shoot phenotype.

Mutants falling within the second class (suppressed rol1-2 phenotype, reduced anthocyanins, Fig. 2H) were expected to be affected in early steps of flavonoid biosynthesis. Indeed, new alleles of tt4 and tt6 were identified among these lines (Fig. 1, Table I).
Mutations in *MYB111* and *FLS1* Underpin the Importance of Flavonols for the *rol1-2* Phenotype

The data obtained so far point towards flavonols being involved in the establishment of the *rol1-2* mutant phenotype. As inhibiting flavonol synthesis is not expected to reduce anthocyanin accumulation (Stracke et al., 2009), a third class of M2 seedlings was selected that suppress the *rol1-2* shoot phenotype in the presence of anthocyanin (Fig. 2I). Among these lines, two were identified to have a mutation in the R2R3-MYB transcription factor gene *MYB111*. MYB111 has been shown to regulate flavonol biosynthesis specifically in cotyledons (Stracke et al., 2007). Flavonol levels were determined as the sum of the areas below the flavonol HPLC-peaks per milligram dry weight of plant material. *rol1-2 myb111* double mutants showed a strong reduction in flavonol levels in the shoot but not the root compared to the wild type or *rol1-2* (Fig. 3A). These *myb111* alleles represent one missense and one nonsense mutation (Table I). Complementation of the *rol1-2 myb111-2* double mutant with a genomic clone of *MYB111* resulted in plants displaying the *rol1-2* shoot phenotype (data not shown). Hence, the point mutations in *myb111* are indeed inducing suppression of the *rol1-2* phenotype.

It was speculated that mutations in the *Flavonol Synthase 1* (*FLS1*) gene, coding for the most active FLS protein of Arabidopsis, should result in a suppressed *rol1-2* shoot phenotype but not inhibit anthocyanin accumulation. Due to this, M2 seedlings of the third class were sequenced at the *FLS1* locus and, indeed, four *fls1* alleles (*fls1*-3 to *fls1*-6) were identified. These represent the first stable *fls1* alleles in the Columbia genetic background in addition to the unstable En-1 *fls1*-1 allele and the *fls1*-2 allele which is in the No-0 genetic background (Wisman et al., 1998; Stracke et al., 2009). The FLS1 protein consists of 336 amino acids. *fls1*-3 introduces a stop at position Q71, *fls1*-4 to *fls1*-6 induce the changes R156K, P291L, and E307K, respectively (Table I, Supplemental Fig. S1). The missense alleles showed suppression of *rol1-2* comparable to the nonsense allele *fls1*-3, indicating that the mutated proteins have a strongly reduced enzymatic activity. FLS1 homologs of different plant species (Arabidopsis, petunia, potato, citrus) show at least 60% identity and over 70% similarity compared to FLS1 of Arabidopsis (Supplemental Fig. S1). P291, changed to L in *fls1*-5, is conserved in all FLS1 homologs, while R156, mutated in *fls1*-4, is conserved except in AtFLS3. By contrast, the position E307,
affected in fls1-6, seems more variable. In fact, the petunia FLS protein has a K at 
this position, as does the fls1-6 allele.

The fls1-3 allele was used for further work. In the rol1-2 fls1-3 seedlings, 
flavonols in shoots and roots were still detectable but strongly reduced (Fig. 3A) to a 
level that was insufficient to induce the rol1-2 shoot phenotype. The strong reduction 
in flavonol biosynthesis resulted in an increase in dihydroflavonols that were available 
for biosynthetic conversion. This led to a stronger accumulation of anthocyanidin in 
rol1-2 fls1-3 seedlings (Fig. 3B). Apart from suppressing the rol1-2 phenotype no 
obvious morphological defect could be observed in the rol1-2 fls1-3 double or fls1-3 
single mutant.

Since reducing the flavonol content had a strong effect on the rol1-2 phenotype, 
we wanted to know whether increasing the amount of flavonols also has an effect on 
the rol1-2 or wild-type phenotype. To this end, wild type and the rol1-2 mutant were 
transformed with the FLS1 genomic clone under the control of the ubiquitously active 
CAULIFLOWER MOSAIC VIRUS 35S (35S) promoter. 35S:FLS1 transgenic plants of 
both lines frequently failed to show normal anthocyanin staining and rather appeared 
pale green, suggesting that the metabolic flux was redirected towards flavonols, 
leaving little intermediates for the synthesis of anthocyanins. The flavonol content 
analysis, however, revealed only subtle changes in 35S:FLS1 overexpressing lines 
compared to non-transformed plants (Supplemental Fig. S2). Also, no morphological 
alterations were observed in the transgenic lines, i.e. FLS1-overexpressing wild type 
and rol1-2 mutants showed the phenotype of their respective non-transgenic mother 
plants.

**RHM1 and FLS1 Expression is Predominant on the Adaxial Side of Cotyledons**

The rol1-2 hyponastic cotyledon phenotype is the result of aberrant cell growth. 
While adaxial epidermal cells are oversized and lack the typical jigsaw puzzle-like cell 
shape (Fig. 4A), abaxial epidermal cells show a wild-type phenotype (Fig. 4B). To 
investigate the cause of this asymmetric growth defect, RHM1 (the protein affected in 
the rol1-2 mutant) was localized in plants. A RHM1-GFP fusion construct under the 
control of the RHM1 promoter and terminator sequence was expressed in the rol1-2 
mutant. This RHM1:RHM1-GFP construct led to complementation of the rol1-2 
mutant, indicating that the fusion protein is biologically active. Analysis of
homozygous transgenic T3 seedlings revealed predominant GFP fluorescence on the adaxial side of cotyledons, in the emerging leaves, and in trichomes, whereas no significant signal could be found on the abaxial side of cotyledons (Fig. 4, C and D). Hence, restriction of the growth defect to the adaxial side of cotyledons in the rol1-2 mutant is due to the asymmetric expression of the endogenous \textit{RHM1}. In the root tip, a GFP signal was found in epidermal cells in the meristematic and elongation zone (Fig. 4E). In the later elongation- and differentiation zone, the signal was detected in all cell layers (Fig. 4, E and F). GFP signal was also observed in elongating root hairs (Fig. 4G), which fits the short-root and short root-hair phenotype of the \textit{rol1-2} mutant (Diet et al., 2006). As described by others (Wang et al., 2009), RHM1 appears to be a cytoplasmic protein (Fig. 4H).

In a next step, a C-terminal \textit{FLS1-GFP} and an N-terminal \textit{GFP-FLS1} construct was expressed in \textit{rol1-2 fls1-3} under the control of the \textit{FLS1} promoter and terminator. For each construct, three independent T3 lines were selected for further analysis. Seedlings of all lines exhibiting GFP fluorescence clearly showed a \textit{rol1-2} phenotype, i.e. complementation of the \textit{fls1-3} mutation, demonstrating that the GFP-FLS1 (Fig. 5, A and B), as well as the FLS1-GFP (not shown) fusion protein is active. GFP fluorescence in these plants was mostly found on the adaxial side of cotyledons, in emerging leaves, shoot-root transition zone, and in trichomes (Fig. 5, D-H). Also in roots, GFP-FLS1 localization overlapped well with the one of RHM1-GFP, except that GFP fluorescence was not observed in epidermal cells. In the root tip, fluorescence was observed in inner columella- and adjacent root cap cells (Fig. 5, I and J). On the abaxial side of cotyledons, only guard cells showed clear GFP activity (Fig. 5K). On the sub-cellular level, FLS1 appears to localize to the cytoplasm as the induction of plasmolysis induced retraction of GFP fluorescence with the plasma membrane (Fig. 5L). Interestingly, GFP-FLS1 also accumulated in the nucleus. Staining of \textit{FLS1:GFP-FLS1} plants with the nuclear dye 4',6-diamidino-2-phenylindole (DAPI) resulted in overlapping fluorescence and consequently a yellow coloring of the nucleus (Fig. 5, M-O). To elucidate a functional role of nuclear FLS1, a nuclear export signal (NES) (Shen et al., 2007) was fused to the N-terminus of GFP-FLS1. The analysis of three independent transgenic \textit{FLS1:NES-GFP-FLS1} lines showed the ability of this construct to rescue the \textit{fls1-3} mutation in a \textit{rol1-2 fls1-3} mutant background (Fig. 5C). Localization of NES-GFP-FLS1 in DAPI stained Arabidopsis
root cells showed effective inhibition of nuclear import of FLS1 and only a cytoplasmic distribution remaining (Fig. 5P). Taken together, these results indicate that nuclear localized FLS1 is dispensable with respect to the induction of the rol1-2 phenotype.

Flavonols Do Not Easily Diffuse between Tissues

Previous reports on flavonol feeding experiments suggested that dihydroflavonols, i.e. dihydrokaempferol and -quercetin, are transported within Arabidopsis seedlings. By contrast, no significant transport of flavonols was observed (Buer et al., 2007). To investigate this issue by a pure *in vivo* approach, flavonol biosynthesis was induced in *rol1-2 fls1-3* double mutants by targeted expression of *FLS1-GFP* followed by monitoring of flavonol distribution. *FLS1-GFP* was expressed under the control of the promoters *MYB111* (active in cotyledons (Stracke et al., 2007)) and *FIL* (active on the abaxial side of cotyledons (Sawa et al., 1999)). For each construct, several transgenic lines were produced and two independent homozygous T3 lines were analyzed in detail. *MYB111:FLS1-GFP* complemented the *fls1-3* mutation, resulting in seedlings exhibiting a *rol1-2* phenotype (Fig. 6, A and B). Analysis of the flavonol content in these lines showed an increase in the shoot, which was expected since MYB111 regulates flavonol biosynthesis in cotyledons and thus is likely to be expressed in the same cells as *FLS1*. By contrast, the flavonol content in roots was not increased, indicating that the flavonols produced in the shoot are not transported to a measurable extent to the root. The *FIL* promoter, inducing expression on the abaxial side of cotyledons, resulted in the accumulation of flavonols (Fig. 6E), but complementation of the *fls1-3* mutation was not observed (Fig. 6, C and D). Surprisingly, the amount of flavonols in the shoot was doubled compared to the *MYB111:FLS1-GFP* transgenic lines. Hence, flavonols can accumulate in tissues where they are normally not found, but transport from these cells seems not to take place.

Auxin Transport in the *rol1-2* Mutant is Affected by Flavonols

Previous work had revealed that the *rol1-2* mutant phenotypes are partly caused by increased auxin concentration in cotyledons and that this effect can be reverted by inhibiting flavonoid biosynthesis (Ringli et al., 2008). Therefore, the effect of flavonols on auxin transport was determined. Because the *rol1-2* mutant develops
significantly different from the wild type which might cause aberrant results in whole seedling auxin transport measurements, a protoplast-based experimental system was chosen. In a first step, expression of the relevant genes had to be assessed in protoplasts. RT-PCR with primers specific for RHM1/ROL1 and FLS1 on RNA isolated from protoplasts indicated that both genes are expressed (Supplemental Fig. S3), which is in agreement with microarray data on protoplasts (Zimmermann et al., 2004).

Protoplasts of six week-old rosette leaves were isolated, loaded with the radioactively labelled auxins, IAA or NAA, and subsequent export of IAA and NAA into the medium was measured. IAA transport was comparable between protoplasts derived from wild-type, rol1-2 and rol1-2 fls1-3 mutant plants (Fig. 7A). By contrast, NAA export was increased in rol1-2 compared to wild-type protoplasts. However, protoplasts of a rol1-2 fls1-3 double mutant showed wild-type NAA export activity (Fig. 7B). Hence, the rol1-2 mutation induces an increase in NAA transport, and inhibiting flavonol accumulation by the fls1-3 mutation relieves this inhibition and leads to wild-type NAA transport levels.

DISCUSSION

An EMS-mutagenesis screen was performed to genetically characterize the cause of the rol1-2 shoot mutant phenotypes. Mutagenized rol1-2 plants with a suppressed, i.e. wild type-like shoot phenotype and a lack of anthocyanin accumulation were affected in an enzymatic step prior to flavonol synthesis such as TT4 and TT6. Plants lacking anthocyanin but still displaying the rol1-2 shoot phenotype were affected in steps downstream of flavonol accumulation such as TT3, TT7 and TT18. This confirms previous findings on tt4 and tt7 (Ringli et al., 2008). It also shows the opportunities of this screen to distinguish between mutants affected in either the upper or the lower part of the flavonoid biosynthesis pathway, taking flavonol biosynthesis as the line separating the two halves of the pathway.

The identification of fls1 and myb111 mutants confirms that flavonols are the causing agents of the developmental defects observed in the rol1-2 mutant. Interestingly, myb111 and fls1 mutants allow for the accumulation of flavonols to 20% and 5%, respectively, compared to rol1-2. Hence, a complete block of flavonol
synthesis as caused by the \textit{tt4} mutation (Ringli et al., 2008) is not required for suppression of \textit{rol1-2}, as no apparent difference in suppression efficiency was detectable between \textit{tt4}, \textit{myb111}, and \textit{fls1}. Similar to \textit{tt4}, mutations in \textit{MYB111} and \textit{FLS1} did not have an effect on the \textit{rol1-2} root phenotype. Hence, the \textit{rol1-2} root phenotype seems induced by the modification in cell wall structures caused by the \textit{rol1-2} mutation (Diet et al., 2006).

The residues affected in the \textit{fls1} alleles appear to alter protein activity to a similar extent since all suppress the \textit{rol1-2} shoot phenotype in a comparable way. FLS proteins belong to the group of 2-oxoglutarate-dependent dioxygenases (2-ODDs) (Prescott and John, 1996; Martens et al., 2010), whose core-domain spans the FLS1 amino acid residues 196-296. None of the missense mutations are within this domain. The alignment of FLS proteins from different plant species revealed that R156, mutated to K in \textit{fls1-4} is completely conserved between FLS1 and FLS of other plant species, but not in FLS3 of Arabidopsis where this position corresponds to I127. FLS3 has been shown to be the only FLS protein beside FLS1 with measurable yet low activity (Preuss et al., 2009). Even though FLS3 lacks homology in different regions that are otherwise conserved among 2-ODD type enzymes (Owens et al., 2008) it is possible that the I127 residue also affects FLS3 activity. It is interesting to note that the petunia FLS contains a K residue encoded by the \textit{fls1-6} allele. Hence, an amino acid that strongly affects the activity of the Arabidopsis FLS1 is present in a genuine and active FLS protein of petunia (Holton et al., 1993). It is possible that this amino acid functions in relation with other parts of the protein that are different between the petunia FLS and Arabidopsis FLS1.

The amount of anthocyanin in \textit{rol1-2 fls1-3} is doubled compared to the wild type, which was shown previously for \textit{fls1-2} in the No-0 genetic background (Stracke et al., 2009). This suggests a redirection of the metabolic flux towards the formation of anthocyanins. On the other hand, this opens the possibility for directing the metabolic flux towards flavonols by reducing anthocyanin formation, as these processes compete for the same substrates. Arabidopsis seedlings have the capacity of accumulating more flavonols as shown by the overexpression of MYB12, a R2R3-MYB transcription factor regulating flavonol biosynthesis genes leading to a 3-4 fold increase in flavonol content (Mehrtens et al., 2005). Here, overexpression of \textit{FLS1} was chosen as an alternative approach to manipulate the flavonol content in
Arabidopsis. Surprisingly, the transgenic lines neither showed an obvious phenotypic change except loss of anthocyanin accumulation nor an increase in flavonol content. This was quite unexpected in the light of the fact that accumulation of anthocyanins was strongly inhibited, suggesting a redirection of the metabolic flux towards flavonols. A model for metabolome formation and metabolic channelling in flavonoid biosynthesis proposed by Winkel (2004) helps to shed light on this phenomenon. According to this model, FLS1 competes with enzymes leading to anthocyanin formation which therefore could be blocked by excessive amounts of FLS1. At the same time, FLS1 appears not to be the limiting factor for flavonol biosynthesis.

The analysis of the cell-specific protein localization by protein-GFP fusion constructs provides an explanation for the observed asymmetric cell-growth phenotype observed in rol1-2 mutants (Diet et al., 2006; Ringli et al., 2008) as expression of RHM1 is limited to the adaxial side of cotyledons. This finding appears to be contradictory to previous studies with RHM1 promoter-GUS fusion constructs (Diet et al., 2006; Wang et al., 2009), which could be explained by the known diffusion of the GUS product. Further, the whole genomic RHM1 sequence was used for GFP localization studies which most likely reflect expression of the endogenous RHM1 more accurately. The expression patterns of RHM1-GFP and GFP-FLS1 are largely overlapping. On the abaxial side, GFP-FLS1 could only be detected in guard cells, where flavonols might have a particular function. Within roots, RHM1-GFP and GFP-FLS1 fluorescence occurs in late elongation and early differentiation zone alike. Hence, RHM1 and FLS1 expression correlate not only on the tissue but also on the cellular level, supporting the finding that RHM1 might be the main supplier of rhamnose for flavonol glycosylation (Yonekura-Sakakibara et al., 2008).

Grafting experiments with reciprocal combination of tt4 and wild-type shoots and roots revealed that endogenous flavonoids are transported from shoot to root and vice versa (Buer et al., 2008). Flavonoid transport experiments performed by external flavonoid application showed that dihydroflavonols are transported in planta, whereas flavonol aglycones are not (Buer et al., 2007). In this study, targeted in situ biosynthesis of flavonols in the rol1-2 fls1-3 genetic background was chosen as a complete in vivo approach to elucidate a potential transport of flavonols. Expressing FLS1-GFP under the control of the MYB111 promoter was expected to be efficient and indeed resulted in complementation of the rol1-2 fls1-3 double mutant, i.e.
development of the rol1-2 shoot phenotypes. Interestingly, driving FLS1-GFP expression with the FIL promoter resulted in even higher levels of flavonols compared to MYB11:FLS1-GFP lines, yet no complementation of the rol1-2 fls1-3 double mutant. Hence, little – if any – flavonols are being transported between the abaxial and adaxial side of cotyledons. The reason for this might be that flavonols remain in the tissue where they are produced. Alternatively, abaxial epidermal cells are not supposed to synthesize flavonols and thus might not be competent to release them to neighbouring tissues.

Flavonoids are known to be non-essential regulators of polar auxin transport (PAT). They accumulate transiently in epidermal cells of the root elongation zone and act in multi-functional ways on PAT (Murphy et al., 2000; Brown et al., 2001; Peer et al., 2001; Peer et al., 2004; Buer et al., 2004; Peer and Murphy, 2006; Peer and Murphy 2007). Beside being versatile modulators of the distribution of auxin efflux facilitating PIN proteins (Santelia et al. 2008), recent work points towards flavonols as modulators of transporters of the B group ATP-binding cassette transporter superfamily (ABCB), another class of auxin efflux transporters (Geisler et al., 2005, Blakeslee et al., 2007). This regulation is thought to be mediated by various processes like protein phosphorylation, protein-protein interaction, vesicular trafficking and binding to the ATP binding pocket of ABCBs (Jacobs and Rubery, 1988; Di Pietro et al., 2002; Titapiwatanakun and Murphy, 2009). Previous analyses have shown that auxin distribution is altered in rol1-2, an effect that correlates with flavonoid accumulation and is absent in the flavonoid-less rol1-2 tt4 double mutant (Ringli et al., 2008). Here, we demonstrate that it is most likely the changed flavonol accumulation pattern in rol1-2 leading to a modified rate of auxin transport and thus an altered auxin distribution. The increased auxin transport from rol1-2 protoplasts is reduced to wild-type levels in rol1-2 fls1-3 protoplasts. The polar localization of PIN proteins has been shown to be altered following modifications of the cell wall (Feraru et al., 2011), which reveals a limitation of the cell wall-free protoplast assay system. Yet, the general transport activity is likely to be correctly reflected and the data fits the general picture of flavonol-modified auxin transport. Interestingly, only export of NAA but not of the native auxin IAA is affected. This suggests that flavonols target a specific subset of the auxin transport machinery as NAA export is not caused by diffusion but is an active process (Delbarre et al., 1998). In recent years, ABCBs
were identified that seem to be involved in NAA transport (Geisler et al., 2005; Cho et al., 2007; Lewis et al., 2009) and these proteins are thus potential targets of flavonols. Although flavonol aglycones are thought to effectively interfere with auxin transport, those were not detectable in our extracts. It is possible, however, that flavonol aglycones accumulate only transiently and to levels that are below the detection limit.

Flavonols accumulate in the nucleus and cytoplasm as are the flavonoid biosynthetic enzymes CHS and CHI (Saslowski et al., 2005; Fig. 1). GFP studies presented in this work show FLS1 being a cytoplasmic and nuclear protein alike. This suggests that the flavonol biosynthetic machinery is also active in the nucleus where flavonols might modulate gene expression (Gilbert and Liu, 2010; Naoumkina and Dixon, 2008). However, excluding FLS1 from the nucleus did not prevent complementation of *fls1-3*, suggesting that nuclear FLS1 activity is not relevant with respect to the *rol1-2* phenotype. In future experiments, it will be necessary to investigate the exact role of FLS1 in the nucleus.

**MATERIALS AND METHODS**

**Plant Material and EMS Mutagenesis**

The *rol1-2* allele used in this study is described in Diet et al. (2006). All lines described in this study are in the Col-0 genetic background. Seeds were surface sterilized with 1% sodium hypochlorite, 0.03% Triton X-100, stratified for 4 d at 4°C and plated on half-strength MS medium containing 0.6% phytagel, 2% sucrose. Plates were put in a vertical orientation in a 16-h light, 8-h dark cycle at 22°C. For propagation and crossings, 10-d-old plants were transferred to soil and grown in a 16-h light, 8-h dark cycle at 22°C and irradiated with 100 μM m⁻² sec⁻¹ white light (Biolux, Osram).

Ethyl methansulfonate (EMS)-mutagenized *rol1-2* seeds were germinated in ten families of 2’500 M1 plants and M2 seeds of each family were pooled. In total, 75’000 M2 seedlings were grown on agar plates in a vertical orientation and screened for their phenotype. Selected mutants (all recessive) were backcrossed with the non-mutagenized *rol1-2* at least three times prior to detailed characterization.
DNA Constructs, Plant Transformation and Molecular Markers

For the *FLS1* complementation construct, the *FLS1* genomic clone was PCR-amplified with the primers 5'-AATTCTACTGAATTGACAGAG-3' and 5'-TAATAGCGAATGTGC GGTTTG-3'. The resulting fragment (*FLS1:FLS1*) was cloned into pGEM-T easy (Promega) for sequencing.

For the GFP fusion constructs, a *Bam* HI was introduced into *FLS1:FLS1* clone by PCR either 3' of the ATG (N-terminal fusion) or 5' of the TGA (C-terminal fusion). A previously produced GFP construct flanked by *Bam* HI sites (Leiber et al., 2010) was cloned into these *Bam* HI sites, resulting in *FLS1:GFP-FLS1* and *FLS1:FLS1-GFP*, respectively. These constructs were cloned into *pART27* by *Not* I (Gleave, 1992) and plants were transformed as described (Diet et al., 2006).

For the construction of *FLS1:NES-GFP-FLS1*, the NES sequence (AACGAGCTTGCTCTTAAGTGGCTGGACTTGATATTAACAAG) was introduced at the 5'-end of *GFP* via PCR. For plant transformation, the construct was cloned in *pART27* by *Not* I.

For the *RHM1-GFP* fusion construct, the genomic clone of *RHM1* encompassing 1.9 kb promoter and 500 bp terminator sequence was amplified by PCR using the primers 5' CACTAAAGATAGAGCATTGAGAAG 3' and 5' GTTGGTATCGAATCCTTTGAGTTC 3' and cloned into pGEM-T easy for sequencing. The GFP clone (Leiber et al., 2010) was introduced 5' adjacent to the stop codon. For plant transformation, the *RHM1:RHM1-GFP* construct was cloned into *pART27* by *Not* I.

The molecular marker for *rol1-2* was described previously (Diet et al., 2006). All alleles were identified by sequencing of candidate genes and comparison with the wild-type DNA. Cleaved-amplified polymorphic sequence markers were established for some of the alleles: *fls1-3*, 5'-GATCTAAGCGATCCCGACGAAG-3' and 5'-CAGAATCTGTAATTGACGCATGAC-3', digested with *Dde* I; *myb111-2*, 5'-GTTGGATCGAATCTTTGAGTTC-3' and 5'-CTCCAATGTTATCTCTCACAATTC-3', digested with *Bcl* I; *myb111-3*, point mutations had to be introduced in one primer (underlined positions) to create a restriction site polymorphism; 5'-AAAGAGGAAATATTACTTCTGCAGACAGACT-3' and 5'-CAGCATTACAGTCATCACCCAC-3', digested with *Bsi* WI.
RT-PCR

Total RNA was extracted from protoplasts or from seedlings grown for 10 d in a vertical orientation using the TRIzol method (Gibco BRL). Two micrograms of each RNA sample were reverse transcribed using oligo(dT) Primer and a Superscript II RNase H reverse transcriptase kit (Invitrogen) following the manufacturer’s recommendations. The resulting cDNA was used to perform a RT-PCR with the primers 5’-GATTCAAGGACATTGAAGGATACG-3’ and 5’-CTCCGATAGCTTCTTACATGCAC-3’, or 5’-CTCGGAATTCTCAATTGTCTTC-3’ and 5’-CTTGAAGTTCGGAGAGTGCTTAG-3’ specific for FLS1 and ROL1/RHM1, respectively. Both primer pairs are flanking intronic sequence to distinguish in the RT-PCR experiment between cDNA and contamination with genomic DNA.

Microscopic Analysis

Light microscopic observations were made using a Leica DM6000 stereomicroscope. Gel prints of epidermal cells were produced following an established protocol (Horiguchi et al., 2006) and observed by differential interference contrast microscopy using a Leica DMR microscope.

Flavonol and Anthocyanidin Content Analysis

For the analysis of the flavonol accumulation profile, seedlings were grown in a vertical orientation for 6 d as described. One hundred intact seedlings were cut in the hypocotyl region, and roots and shoots were pooled separately, frozen in liquid nitrogen, and lyophilized to determine the dry weight. The dried material was incubated in 500 μL of 80% methanol overnight at 4°C and subsequently macerated with a pestle, followed by vigorous vortexing. After pelleting the cell debris by centrifugation, the supernatant was transferred to a fresh tube and evaporated in a Speed-Vac centrifuge, with the temperature being limited to a maximum of 42°C. After evaporation, the pellet was resuspended in 100 μL of fresh 80% methanol and used for analysis. HPLC-ESI-MS and MSMS experiments were performed on an Acquity UPLC (Waters) connected to a Bruker maXis high-resolution quadrupole time-of-flight mass spectrometer (Bruker Daltonics). An Acquity BEH C18 HPLC column (1.7 μm, 2.1x100 mm fitted with a 2x2 mm guard column) was used with a
gradient of solvent A (H₂O, 0.1% (v/v) HCOOH) and solvent B (CH₃CN, 0.1% (v/v) HCOOH) (0.45 mL flow rate, linear gradient from 5 to 95% B within 30 min).

The mass spectrometer was operated in the negative electrospray ionization mode at 3'500 V capillary voltage, –500 V endplate offset, with a N₂ nebulizer pressure of 1.3 bar and dry gas flow of 8.0 L/min at 200°C. MS acquisitions were performed in the full scan mode in the mass range from m/z 50 to 2000 at 25'000 resolution (full width at half maximum) and 2 scans per second. The MS instrument was optimized for maximum signal intensities of Quercitrine at m/z 447. Masses were calibrated with a 2 mM solution of sodium formate over m/z 180 up to 1472 mass range prior to analysis. The lock mass signal of hexakis (1H,1H,2H-perfluoroethoxy)phosphazine at m/z 556.00195 was further used as lock mass during the HPLC run. The area under each flavonol peak was used for relative quantification. The sum of all peak areas represented the relative total amount of flavonols, which was divided by the amount of plant material used for extraction. These values were compared between different plant lines.

Spectrophotometric determination of anthocyanidin levels was performed according to Solfanelli et al. (2006) except some minor changes. Material of 10-d-old seedlings was lyophilized overnight. Three independent biological replicates were used for every genotype. Per mg dry weight, 200 μL extraction solution containing 18% 2-propanol and 1% HCl was added and the samples incubated 10 min at 90°C. After centrifugation for 5 min, 13’000 rpm, the extracts were recovered and absorption determined at 535 nm.

Auxin Transport Experiments

Arabidopsis mesophyll protoplasts were prepared from rosette leaves of plants grown on soil under 100 μM m⁻² sec⁻¹ white light, 8-h light, 16-h dark cycle at 22°C. Intact protoplasts were isolated as described (Geisler et al., 2003) and loaded by incubation with 1 μL mL⁻¹ ³H-IAA (specific activity 20 Ci mM⁻¹; American Radiolabeled Chemicals), or 4-³H-1-naphthalene acetic acid (25 Ci mM⁻¹; American Radiolabeled Chemicals) on ice. External radioactivity was removed by separating protoplasts using a 50–30–5% percoll gradient. Samples were incubated at 25°C and efflux halted by silicon oil centrifugation. Retained and effluxed radioactivity was
determined by scintillation counting of protoplast pellets and aqueous phases. Efflux experiments were performed with three to five independent protoplast preparations with four replicas for each time point.

Accession Numbers

Sequence data from this article can be found in the Arabidopsis Genome Initiative or GenBank/EMBL databases under the following accession numbers: RHM1, At1g78570; for all other genes, see Table I.

Supplemental Material

The following materials are available in the online version of this article.

Supplemental Figure S1. Alignment of FLS protein sequences of different plant species.

Supplemental Figure S2. RT-PCR data, anthocyanidin and flavonol content of 35S:FLS1 transgenic lines.

Supplemental Figure S3. Expression of RHM1/ROL1 and FLS1 in protoplasts.

ACKNOWLEDGMENTS

We would like to thank Anja Meury and Vincent Vincenzetti for valuable technical assistance and Bruno Müller for providing plant material for protoplast preparations.

FIGURE LEGENDS

Figure 1. Sketch of the flavonoid biosynthesis pathway. Bold arrows indicate the different steps leading to flavonoid formation. Names of mutants affected in the biosynthetic process are written in lowercase. CHS chalcone synthase, CHI chalcone isomerase, F3H flavonol 3-hydroxylase, FLS flavonol synthase, F3’H flavonol 3’-hydroxylase, DFR dihydroflavonol-4-reductase, LDOX leucoanthocyanidin dioxygenase, GTs glycosyltransferases. Adopted from Routaboul et al. (2006).

Figure 2. Phenotype of rol1-2 compared to wild type and identified classes of suppressor mutants. The rol1-2 mutant shows hyponastic bending of cotyledons (A) adaxial pavement cells with straight cell borders (B) and deformed trichomes (C) whereas the wild type shows epinastic bending of cotyledons (D), a jigsaw puzzle-like structure of adaxial pavement cells (E), and normal-shaped trichomes (F). Three classes of mutants were identified in this study: No anthocyanin accumulation and no suppression (G), no anthocyanin accumulation and suppression (H), and anthocyanin formation and suppression (I). Bars = 1 mm (A, C, D, F, G, H, I); 40 μm (B and E).

Figure 3. Analysis of relative flavonol and anthocyanidin content. A, comparison of shoot and root flavonol contents of wild type, the rol1-2 single mutant line, the rol1-2 fls1-3 suppressor line and the rol1-2 myb111-2 suppressor line. The sum of the areas under all flavonol peaks was taken as relative measure. B, relative anthocyanidin content (wild-type Columbia set to 100%) is unchanged in rol1-2 and doubled in the rol1-2 fls1-3 suppressor line.

Figure 4. The rol1-2 cell shape phenotype and localization of RHM1-GFP. Adaxial epidermal cells of 6 d old rol1-2 seedlings lack the jigsaw puzzle-like shape (A), whereas the abaxial cells are wild type-like (B). rol1-2 mutants transformed with RHM1:RHM1-GFP showed complementation and revealed fluorescence on the adaxial side of cotyledons (C) as like in emerging leaves and trichomes (D). In roots, GFP fluorescence was observed in epidermal cells of the meristematic and elongation zone whereas in the late elongation zone, RHM1-GFP was detected in all cell layers (E). F shows the differentiation zone where the GFP signal occurred in all tissues and (G) in emerging root hairs. DAPI staining of DNA and merging with the
GFP data indicate a cytoplasmic localization of RHM1-GFP (H). Bars = 1 mm (C, D); 40 μm (A, B); 50 μm (E, F); 20 μm (G, H).

**Figure 5.** Complementation of *fls1-3* and localization of GFP-FLS1. The shoot phenotype of *rol1-2* is suppressed in *rol1-2 fls1-3* (A). The introduction of a GFP-FLS1 construct (B) as well as the introduction of *FLS1:NES:GFP:FLS1* (C) in a *rol1-2 fls1-3* background led to the induction of the *rol1-2* phenotype. GFP-FLS1 was detected on the adaxial side of cotyledons (D and E), in emerging leaves, the root-shoot transition zone (F and G) and in trichomes (H). In the root tip (I) GFP signal was restricted to inner columella cells, adjacent inner lateral root cap cells and late elongation zone. J shows GFP-FLS1 fluorescence in the differentiation zone. On the abaxial side of cotyledons, fluorescence was specifically detected in guard cells (K). L shows plasmolysis of epidermal cells induced by 0.6 M mannose treatment. Magnification of a root cortex cell (M), staining of the nucleus with DAPI (N) and merging of both signals (O) indicate also a nuclear localization of FLS1-GFP. In *NES-GFP-FLS1* transgenic lines, FLS1 is located in the cytoplasm whereas nuclear accumulation is prevented as merged GFP and DAPI data (P) show no overlay. Bars = 1 mm (A-G), 50 μm (H and I); 20 μm (J-L), 5 μm (M-P).

**Figure 6.** Ectopic expression of *FLS1-GFP* in a *rol1-2 fls1-3* background. A and B show shoot phenotypes of a *rol1-2 fls1-3* line transformed with a *MYB111:FLS1-GFP* construct. C and D, phenotype of a *FIL:FLS1-GFP* transgenic *rol1-2 fls1-3* line. E, the flavonol content is specifically increased in shoots of *MYB111:FLS1-GFP* transgenic lines in a *rol1-2 fls1-3* background. In the case of *FIL:FLS1-GFP* transgenic lines, flavonols accumulate in shoots and roots alike. Bars = 1 mm (A and C), 40 μm (B and D).

**Figure 7.** Auxin export from Arabidopsis mesophyll protoplasts. A, IAA export is not significantly altered in *rol1-2* and *rol1-2 fls1-3* compared to the Col-0 wild type. B, NAA export is significantly increased in *rol1-2* and reduced to wild type levels in *rol1-2 fls1-3*.
