Abstract

A balanced sampling design has the interesting property that Horvitz–Thompson estimators of totals for a set of balancing variables are equal to the totals we want to estimate, therefore the variance of Horvitz–Thompson estimators of variables of interest are reduced in function of their correlations with the balancing variables. Since it is hard to derive an analytic expression for the joint inclusion probabilities, we derive a general approximation of variance based on a residual technique. This approximation is useful even in the particular case of unequal probability sampling with fixed sample size. Finally, a set of numerical studies with an original methodology allows to validate this approximation.

Keywords: Sampling design; Balanced sampling; Unequal probability sampling; Variance approximation; Variance estimation; Sampling theory; Sample surveys; Sample; Sampling unequal probability

1. Introduction

A sample is said to be balanced on a set of balancing variables if the estimated totals of these variables are equal to the population totals. Several partial solutions had been presented in Deville et al. (1988), Deville (1992), Ardilly (1991), Hedayat and Majumdar (1995), and Valliant et al. (2000). The cube method proposed by Deville and Tillé (2002) provides a general non-enumerative solution to select balanced samples, and has been used at the Institut National de la Statistique et des Études
Économiques (INSEE, French Bureau of Statistics) for its most important statistical projects: the renovated continuous census and the master sample (on this topic see Dumais and Isnard, 2000; Wilms, 2000). The use of balanced sampling in several projects has dramatically improved efficiency, allowing the reduction of the variance from 20% to 90% comparatively to simple random sampling in some cases (see for instance Deville et al., 1988).

An important question is the derivation of the variance of total estimators under balanced sampling. In balanced sampling it is hard to derive an analytic expression for balanced sampling. Firstly, we propose a class of approximations of the variance derived from theoretical arguments. These approximations are based on a residual technique and are related to previous works: Yates (1949), Hájek (1964, Chapters 4, 7 and 14), and Brewer (2002, Chapter 9).

These approximations show that the variance depends only on the residuals for a particular regression of the interest variable against the balancing variables. The variance is then equal to zero under a linear deterministic model. Secondly, we check the approximation by means of a set of numerical studies. We examine several cases of balanced sampling, and we look for the worst interest variable, i.e. the variable for which the approximation gives the largest overevaluation or underevaluation. We show that in most cases, the error due to the approximation does not exceed 10% of the value of the variance.

The notation is defined in Section 2. A class of variance approximations is given in Section 3. An original and new methodology to evaluate the accuracy of balanced design is developed in Section 4. In Section 5, we present the results of the numerical study. The question of estimation of the variance is discussed in Section 6. Mathematical technicalities are given in the appendices.

2. Balanced sampling

Consider a finite population $U$ of size $N$ whose units can be identified by a label $k \in \{1, \ldots, N\}$. The aim is to study the interest variable $y$ that takes the values $y_k$, $k \in U$, on the units of the population. More precisely, we want to estimate the total $Y = \sum_{k \in U} y_k$. Suppose also that $p$ balancing variables $x_1, \ldots, x_p$ are available, i.e. that the vectors of values $x_k = (x_{k1} \ldots x_{kj} \ldots x_{kp})'$ taken by the $p$ balancing variables are known for all the units of the population. Moreover, without loss of generality, the $p$ vectors $(x_{1j} \ldots x_{kj} \ldots x_{Nj})'$, $j = 1, \ldots, p$, are assumed linearly independent.

A sampling design $p(.)$ is a probability distribution on the set $\Omega$ of all the subsets of $U$ such that $\sum_{s \in \Omega} p(s) = 1$. The random sample $S$ takes a value $s$ with probability $\Pr(S = s) = p(s)$. The inclusion probability of unit $k$ is the probability that unit $k$ is in the sample $\pi_k = \Pr(k \in S)$ and the joint inclusion probability is the probability that two distinct units are together in the sample $\pi_{kl} = \Pr(k \text{ and } l \in S)$. The Horvitz–Thompson estimator given by $\hat{Y} = \sum_{k \in S} y_k/\pi_k$ is an unbiased estimator of $Y$. The Horvitz–Thompson estimator of the $j$th auxiliary balancing total $X_j = \sum_{k \in U} x_{kj}$ is $\hat{X}_j = \sum_{k \in S} x_{kj}/\pi_k$. With a vectorial notation, the Horvitz–Thompson estimator vector $\hat{X} = \sum_{k \in S} x_k/\pi_k$, estimates without bias $X = \sum_{k \in U} x_k$. 
We assume that \( p(s) \) is a balanced sampling design defined as follows.

**Definition 1.** A sampling design \( p(s) \) is said to be balanced on the variables \( x_1, \ldots, x_p \), if and only if it satisfies the balancing equations given by

\[
\hat{X} = X
\]  

which can also be written as

\[
\sum_{k \in s} x_{kj} \pi_k = \sum_{k \in U} x_{kj}
\]

for all \( s \in \Omega \) such that \( p(s) > 0 \), and for all \( j = 1, \ldots, p \), or in other words

\[
\text{var}(\hat{X}) = 0.
\]

**Remark.** If the \( y_k \) are linear combinations of the \( x_k \), i.e. \( y_k = x_k' b \) for all \( k \), where \( b \) is a vector of constants, then \( \text{var}(\hat{Y}) = 0 \). More generally, if the \( y_k \) are well explained by the \( x_k \), one can expect that \( \text{var}(\hat{Y}) \approx 0 \).

Consider now the three following particular cases of balanced sampling.

**Example 1.** A sampling design of fixed sample size \( n \) is balanced on the variable \( x_k = \pi_k \), \( k \in U \):

\[
\sum_{k \in S} \frac{x_k}{\pi_k} = \sum_{k \in U} 1 = \sum_{k \in U} \pi_k = n.
\]

**Example 2.** Suppose that the design is stratified and that in each stratum \( U_h \), \( h = 1, \ldots, H \), of size \( N_h \) a simple random sample of size \( n_h \) is selected, then the design is balanced on variables \( \delta_{kh} \) of values

\[
\delta_{kh} = \begin{cases} 
1 & \text{if } k \in U_h, \\
0 & \text{if } k \notin U_h.
\end{cases}
\]

In this case, we have

\[
\sum_{k \in S} \frac{\delta_{kh}}{\pi_k} = \sum_{k \in U} \delta_{kh} \frac{N_h}{n_h} = N_h
\]

for \( h = 1, \ldots, H \).

**Example 3.** In sampling with unequal probabilities, the Horvitz–Thompson estimator \( \hat{N}_{\pi} = \sum_{k \in S} 1/\pi_k \) of the population size \( N \) is generally random. When the population size is known before selecting the sample, it could be interesting to select a sample such as

\[
\sum_{k \in S} \frac{1}{\pi_k} = N.
\]

Eq. (2) is a balancing equation, where the balancing variable is \( x_k = 1 \), \( k \in U \).
Thus, stratified and unequal probability sampling are particular cases of balanced sampling. Nevertheless, an intricate problem with balanced sampling is that, in most of the cases, the balancing equations (1) cannot be exactly satisfied. Consider the following example.

**Example 4.** Suppose that $N = 10$, $n = 7$, $\pi_k = \frac{7}{10}$, $k \in U$, with $x_k = k$, $k \in U$. Then a balanced sample is such that

$$\sum_{k \in S} k = \sum_{k \in U} k,$$

that implies that

$$\sum_{k \in S} k = 55 \times \frac{7}{10} = 38.5$$

which is impossible as 38.5 is not an integer. The problem arises from the non-integer value of $1/\pi_k$, and from the small population size.

The previous example displays a problem of balanced sampling: there are situations where balanced equations cannot be exactly satisfied (see designs 7–9 in Section 5).

**Remark 1.** A balanced sampling design $p(.)$ with inclusion probabilities $\pi=(\pi_1,\ldots,\pi_N)'$ can be exactly balanced, if given a set of auxiliary variables, there exists at least a set of balanced sample $s_1,\ldots,s_m$ such that

$$\sum_{\ell=1}^m s_{\ell} = \pi.$$  \hfill (3)

If condition (3) is not satisfied, then the sampling design cannot be exactly satisfied. There might exist a rounding problem that precludes meeting the constraints.

3. Variance approximations

The variance of the Horvitz–Thompson estimator is

$$\text{var} (\hat{Y}) = \sum_{k \in U} \sum_{\ell \in U} \frac{y_k y_k}{\pi_k \pi_\ell} \Delta_{k\ell},$$ \hfill (4)

where

$$\Delta_{k\ell} = \begin{cases} 
\pi_{k\ell} - \pi_k \pi_\ell & \text{if } k \neq \ell \\
\pi_k (1 - \pi_k) & \text{if } k = \ell 
\end{cases}$$

and $\Delta = [\Delta_{k\ell}]$. Matrix $\Delta$ will be called the variance–covariance operator. Thus the variance of $\hat{Y}$ can be expressed and estimated by using the joint (order two) inclusion probabilities.

Nevertheless, in the case of Poisson sampling, which is a sampling design with no balancing variables, the variance of $\hat{Y}$ is easy to derive and can be estimated because
only first-order inclusion probabilities are needed. If \( \tilde{S} \) is the random sample selected by a Poisson sampling design and \( \tilde{q}_{EMk}, k \in U \), are the first-order inclusion probabilities of the Poisson design, then

\[
\text{var}_{\text{poiss}}(\hat{Y}) = \text{var}_{\text{poiss}} \left( \sum_{k \in S} \frac{y_k}{\pi_k} \right) = \sum_{k \in U} \frac{y_k^2}{\pi_k^2} \tilde{\pi}_k (1 - \tilde{\pi}_k) = \mathbf{z}' \tilde{\Lambda} \mathbf{z},
\]  

(5)

where \( \mathbf{z} = (z_1 \ldots z_k \ldots z_N)' \), \( z_k = y_k/\pi_k \), and \( \tilde{\Lambda} = \text{diag}[\{\tilde{\pi}_k(1 - \tilde{\pi}_k)\}] \). Note that expression (5) contains \( \pi_k \), and \( \tilde{\pi}_k \), because the variance of the usual estimator (function of \( \pi_k \)'s) is computed under Poisson sampling (function of \( \tilde{\pi}_k \)'s). The \( \pi_k \)'s are always known, but the \( \tilde{\pi}_k \)'s are not necessarily known.

Actually Poisson sampling maximizes the entropy measure:

\[
I(p) = -\sum_{s \subset U} p(s) \log p(s)
\]  

(6)

under the constraints that \( \sum_{s \ni k} p(s) = \tilde{\pi}_k, k \in U \). In the case of exact balanced sampling, we have the following theorem.

**Theorem 1.** Let \( p_{bal}(\cdot) \) be an exact balanced sampling design with inclusion probabilities \( \pi_k, k \in U \), then

(i) There exists a unique maximum entropy sampling design \( p(s) \) with inclusion probabilities \( \pi_k \).

(ii) Let \( \mathbf{c} = A \pi_0 \), in \( \mathbb{R}^p \), where \( \pi_0 \) is an interior point of \( C = [0, 1]^N \), \( A = (a_1 \ldots a_k \ldots a_N) \) and \( a_k = x_k/\pi_k, k \in U \). There exists a uniquely defined Poisson sampling design \( \tilde{p}^*(\cdot) \) with inclusion probabilities \( \tilde{\pi}_k \) such that \( p(.) \) is the conditional of \( \tilde{p}^*(\cdot) \) conditionally to \( \sum_{k \in S} x_k/\pi_k = \mathbf{X} \) and that

\[
E_{\tilde{p}^*} \left( \sum_{k \in S} \frac{x_k}{\pi_k} \right) = \mathbf{c},
\]

where \( E_{\tilde{p}^*}(\cdot) \) is the expectation under the sampling design \( \tilde{p}^*(\cdot) \). In particular, one can take

\[
\mathbf{c} = \mathbf{X} = \sum_{k \in U} \mathbf{x}_k.
\]

The proof is given in Appendix B. It is important to point out that the inclusion probabilities \( \tilde{\pi}_k \) of the sampling design \( \tilde{p}^*(\cdot) \) are generally unknown, except for the balanced sampling design described in Chen et al. (1994)

If we suppose that, through Poisson sampling, the vector \((\hat{Y} \hat{X}')\)' has approximately a multinormal distribution, we obtain

\[
\text{var}_{\text{poiss}}(\hat{Y} | \hat{X} = \mathbf{X}) \approx \text{var}_{\text{poiss}}(\hat{Y} + (\mathbf{X} - \hat{X})' \beta),
\]  

(7)
where

\[ \beta = \text{var}_{\text{poiss}}(\hat{X})^{-1} \text{cov}_{\text{poiss}}(\hat{X}, \hat{Y}), \]

\[ \text{var}_{\text{poiss}}(\hat{X}) = \sum_{k \in U} \frac{x_k x'_k}{\pi_k^2} \tilde{\pi}_k (1 - \tilde{\pi}_k) \]

and

\[ \text{cov}_{\text{poiss}}(\hat{X}, \hat{Y}) = \sum_{k \in U} \frac{x_k y_k}{\pi_k^2} \tilde{\pi}_k (1 - \tilde{\pi}_k). \]

Again \text{var}_{\text{poiss}}(\hat{X}) and \text{cov}_{\text{poiss}}(\hat{X}, \hat{Y}) is a function of \( \pi_k \) and \( \tilde{\pi}_k \), because we compute the variance of the usual Horvitz–Thompson estimator (function of \( \pi_k \)) under the Poisson sampling design (function of \( \tilde{\pi}_k \)).

Observing that \( \hat{X} = As \) and \( \hat{Y} = z's \), where \( s \) is a vector of \( \mathbb{R}^N \) whose units take the value 1 if \( k \in s \) and 0 if \( k \notin s \), by (7) implies

\[ \text{var}(\hat{Y}|\hat{X} = X) \approx z'(I - P')\tilde{\Lambda}(I - P), \]

where \( P' = A'(A\tilde{\Lambda}A')^{-1}A\tilde{\Lambda} \) i.e. that \((I - P')\) is the orthogonal projector on Ker \( A \) according to the metrics defined by \( \tilde{\Lambda} \), where

\[ \text{Ker} \ A = \{u \in \mathbb{R}^N | Au = 0 \}. \]

If

\[ b_k = \tilde{\pi}_k (1 - \tilde{\pi}_k), \]

expression (7) can also be written as

\[ \text{var}_{\text{app}}(\hat{Y}) = \sum_{k \in U} b_k (z_k - \tilde{z}_k)^2, \quad (8) \]

where

\[ \tilde{z}_k = a'_k \left( \sum_{\ell \in U} b_{\ell} a_{\ell} a'_{\ell} \right)^{-1} \sum_{\ell \in U} b_{\ell} a_{\ell} z_{\ell} = [A'(A\tilde{\Lambda}A')^{-1}A\tilde{\Lambda}z]_k \]

is a regression predictor of \( z_k \) for the suitable regression such that \( z_k - \tilde{z}_k \) appears as a residual. When only one balancing variable \( x_k = \pi_k \) is used, (see Example 1), \( \tilde{z}_k \) is simply the mean of the \( z_k \) with the weights \( b_k \). Unfortunately, the weights \( b_k \) are unknown, because they depend on \( \tilde{\pi}_k \)'s, which are not exactly equal to the \( \pi_k \). We propose to approximate the \( b_k \).

Note that expression (8) can also be written

\[ \text{var}_{\text{app}}(\hat{Y}) = z'\Delta_{\text{app}}z, \]

where \( \Delta_{\text{app}} = \{\Delta_{\text{app}k\ell}\} \) is the approximated variance operator where

\[ \Delta_{\text{app}k\ell} = \begin{cases} 
  b_k - b_k a'_k \left( \sum_{i \in U} b_i a_i a'_i \right)^{-1} a_k b_k, & k = \ell, \\
  b_k a'_k \left( \sum_{k \in U} b_k a_k a'_k \right)^{-1} a_k b_\ell, & k \neq \ell. 
\end{cases} \quad (9) \]
In Appendix C, we show that the proposed approximation is still valid for non-exact balanced sampling.

Four variance approximations will be tested numerically. All of them are obtained by various definitions of the $b_k$’s. These four definitions are denoted $b_{k1}$, $b_{k2}$, $b_{k3}$, and $b_{k4}$, and permit the definition of four variance approximations denoted $V_x, x=1,2,3,4$ and four variance operators denoted $\Delta_x, x=1,2,3,4$ by replacing in (8) and (9), $b_k$ by, respectively, $b_{k1}$, $b_{k2}$, $b_{k3}$, and $b_{k4}$.

(1) The first approximation is obtained by considering that at least for large sample size, $\pi_k \approx \tilde{\pi}_k, k \in U$. Thus we take $b_{k1} = \pi_k (1 - \pi_k)$.

(2) The second approximation is obtained by applying a correction for loss of degrees of freedom

$$b_{k2} = \pi_k (1 - \pi_k) \frac{N}{N - p}.$$

This correction allows obtaining the exact expression for simple random sampling with fixed sample size.

(3) The third approximation derives from the fact that the diagonal elements of the variance operator $\Delta$ of the true variance are always known and are equal to $\pi_k (1 - \pi_k)$. Thus by defining

$$b_{k3} = \pi_k (1 - \pi_k) \frac{\text{trace} \Delta}{\text{trace} \Delta_1},$$

we can define the approximated variance operator $\Delta_3$ that has the same trace as $\Delta$.

(4) Finally, the fourth approximation derives from the fact that the diagonal elements $\Delta_{\text{app}}$ can be computed and is given in (9). The $b_{k4}$ are constructed in such a way that $\Delta_{x4} = \Delta_{\text{app}x4}$, or in other words that

$$\pi_k (1 - \pi_k) = b_k - b_k a_k^t \left( \sum_{k \in U} b_k a_k a_k^t \right)^{-1} a_k b_k, k \in U. \quad (10)$$

The determination of the $b_{k4}$ requires then the resolution of the non-linear equation system. This fourth approximation is the only one that provides the exact variance expression for stratification. A similar idea was already proposed by Hájek (1981, p. 26) for the fixed size constraint. However, there is a condition given by the following theorem.

**Theorem 2.** For the fixed sample size constraint ($p = 1, x_k = \pi_k, a_k = 1$ for all $k \in U$), a necessary condition in order that a solution exists in (10) is that

$$\max_k \frac{\pi_k (1 - \pi_k)}{\sum_{\ell \in U} \pi_{\ell} (1 - \pi_{\ell})} < \frac{1}{2}.$$

The proof is given in Appendix D.

Fortunately, this condition holds rarely and has never appeared in the numerical study.
4. Measure of accuracy of the approximations of variance

The aim of numerical study is the evaluation of the approximation of variance for balanced sampling. The methodology is unusual because we do not evaluate an estimator but an approximation of an interest function. Moreover, our methodology consists of identifying the worst population vector of interest for a given sampling design. The worst vector is the one that provides the largest difference between the approximation and the true variance.

In the numerical study, the samples are generated by means of the cube method. This method is divided into a flight phase and a landing phase (see Deville and Tillé, 2002). Each phase can be applied with several options. For the flight phase, at each step of the algorithm, the direction has been selected in Ker A randomly by means of vector of independent standard reduced normal variables, which intuitively provides a large entropy to the sampling design. At the landing phase, the sample is selected by means of a linear program.

The $\pi_k$, $\pi_k'$ and $\Lambda = [\pi_k' - \pi_k \pi_\cdot]$ are estimated by means of 10000 iterations, these estimations are denoted, respectively, $\tilde{\pi}_k$, $\tilde{\pi}_k'$ and $\tilde{\Lambda}$. It is essential to use at least 10000 iterations. For example, if $\pi_k = 0.5$, then

$$\text{var}(\tilde{\pi}_k) = \frac{(0.5)^2}{10000} = (0.005)^2,$$

the length of the confidence interval of probability 0.95 is thus $2 \times 1.96 \times 0.005 \approx 0.02$. So, only a two-digit precision is ensured.

If $V$ denotes the true variance i.e. $V = \text{var}(\tilde{Y}) = z'\Lambda z$, then the quality of a variance approximation could be measured by

$$R_x = \frac{\hat{V}_x}{V} = \frac{z'\hat{\Lambda}_x z}{z'\Lambda z}, \quad x = 1, 2, 3, 4$$

and is estimated by means of a numerical study by

$$\hat{R}_x = \frac{\hat{V}_x}{\hat{V}} = \frac{z'\hat{\Lambda}_x z}{z'\hat{\Lambda} z}, \quad x = 1, 2, 3, 4,$$

where $\hat{\Lambda}_x$ denotes an estimation of $\Lambda_x$ obtained by replacing the $\pi_k$ by the $\tilde{\pi}_k$ in expression (8). Estimator $\hat{V}_x/\hat{V}$, which is a ratio, is preferred to $V_x/\hat{V}$, that could also be computed.

The extreme values of $\hat{R}_x$ are given by

$$\max_z z'\hat{\Lambda}_x z \quad \text{subject to } z'\hat{\Lambda} z = \text{Constant}$$

and

$$\min_z z'\hat{\Lambda}_x z \quad \text{subject to } z'\hat{\Lambda} z = \text{Constant}$$

which gives $\hat{\Lambda}_x z = \hat{\lambda}\hat{\Lambda} z$ where $\hat{\lambda}$ is the Lagrange multiplier. The problem consists of finding the decomposition of $\hat{\Lambda}_x$ in $\hat{\Lambda}$. Let $\hat{\lambda}_i$ be the $i$th eigenvalue of this decomposition (on this topic see Gabler, 1984; Harville, 1997, pp. 562, 581). Since $\hat{\Lambda}_x$ has
p eigenvalues equal to zero, then \( \max_z \tilde{\mathbf{R}}_x = \lambda_1 \) and \( \min_z \tilde{\mathbf{R}}_x = \lambda_{N-p} \). Note that if \( \text{trace} \mathbf{A}_x = \text{trace} \mathbf{A} \), (this is the case for \( x = 3 \) and 4) then

\[
\frac{1}{N} \sum_{i=1}^{N} \lambda_i = 1.
\]

These two eigenvalues \( \lambda_{\max} = \lambda_1 \) and \( \lambda_{\min} = \lambda_{N-p} \) represent the worst cases for which the approximation gives, respectively, the largest overestimation or underestimation of the true variance. A good approximation should thus have a corresponding \( \lambda_{\max} \) and \( \lambda_{\min} \) very close to 1.

5. Results of the numerical studies

Except in the equal probability cases, the inclusion probabilities are generated by using the square of centered reduced normal variables (chi-square distribution with one degree of freedom). Nine numerical studies were carried out with balanced designs corresponding to the particular applications given in the previous sections. In some cases, the balancing equations can be exactly satisfied, in others not. Several applications are made on very small population sizes, which should provide the worst cases for the variance approximation.

**Balanced design 1:** Balancing the moments of the order number. The design has equal probabilities with \( N = 40, n = 15, p = 4, x_{k1} = 1, x_{k2} = k, x_{k3} = 1/k, \) and \( x_{k4} = 1/k^2, \) where \( k = 1, \ldots, N, \) is the order number. This sampling design is an exact balanced sampling design.

**Balanced design 2:** Triangular overlapping stratification. The design is defined by \( N = 30, E(n) = 10, p = 3, \)

\[
\begin{align*}
x_{k1} &= \begin{cases} 
1, & k \in \{1, \ldots, 15\}, \\
0, & k \not\in \{1, \ldots, 15\},
\end{cases} \\
x_{k2} &= \begin{cases} 
1, & k \in \{11, \ldots, 25\}, \\
0, & k \not\in \{11, \ldots, 25\},
\end{cases} \\
x_{k3} &= \begin{cases} 
1, & k \in \{21, \ldots, 30\} \cup \{1, \ldots, 5\}, \\
0, & k \not\in \{21, \ldots, 30\} \cup \{1, \ldots, 5\}.
\end{cases}
\end{align*}
\]

This sampling design is not an exact balanced sampling design.

**Balanced design 3:** Cross-stratification or balanced quota sampling I. The design has equal probabilities with \( N = 40, n = 10. \) The constraints are the marginal totals of a \( 4 \times 10 \) contingency table. The balancing equations can be exactly satisfied.

**Balanced design 4:** Cross-stratification or balanced quota sampling II. The design has equal probabilities with \( N = 60, n = 12. \) The constraints are the marginal totals of a \( 5 \times 12 \) contingency table (cross-stratification or balanced quota sampling). This sampling design is an exact balanced sampling design.

**Balanced design 5:** Cross-stratification or balanced quota sampling III. The design has unequal probabilities with \( N = 48, n = 12. \) The constraints are the marginal totals of a \( 3 \times 4 \) contingency table (cross-stratification or balanced quota sampling). This sampling design is an exact balanced sampling design.

Balanced design 6: Two overlapping strata. The design has equal probabilities with $N = 30$, $E(n) = 15$, $p = 2$, $x_{k1} = \{1, \ldots, 20\}$, $x_{k2} = \{1, \ldots, 30\}$.

This sampling design is an exact balanced sampling design.

Balanced design 7: Small population size. The design has equal probabilities with $N = 10$, $n = 5$, $p = 4$. This sampling design is not an exact balanced sampling design.

Balanced design 8: The design is Balanced on $n$ and $N$ with very small population size I, $N = 8$, $n = 3$, $p = 2$, $x_{k1} = \pi_k$, $x_{k2} = 1$. This sampling design is not an exact balanced sampling design.

Balanced design 9: The design is Balanced on $n$ and $N$ with very small population size II, $N = 12$, $n = 5$, $p = 2$, $x_{k1} = \pi_k$, $x_{k2} = 1$. This sampling design is not an exact balanced sampling design.

Table 1 gives the smallest and the largest eigenvalues $\lambda_{\min}$ and $\lambda_{\max}$, for $x = 1, 2, 3, 4$. In almost all the cases, the $\Lambda_4$ is the best approximation. Even when the balancing equations are not exactly satisfied, the ratio $z'\Lambda_4z/(z'\Lambda z)$ remains close to 1. Note that $\lambda_{\min}$ and $\lambda_{\max}$ correspond to the worst ratio, the approximation will thus be better in any practical case. The correction for the loss of degrees of freedom can be important when the population size is small.

6. Variance estimation

In this section, we propose an estimator of (8). As (8) is a function of totals, we can substitute each total by its Horvitz–Thompson estimator (Deville, 1999). The resulting estimator for (8) is

$$\hat{\text{var}}(\hat{Y}) = \sum_{k \in S} c_k (z_k - \hat{z}_k)^2,$$

(12)
where
\[ \hat{z}_k = a_k' \left( \sum_{i \in S} c_i a_i' \right)^{-1} \sum_{i \in S} c_i a_i z_i \]
is the estimator of the regression predictor of \( z_k \).

Note that (12) can also be written as
\[ \sum_{k \in S} \sum_{\ell \in S} z_k D_{k \ell} z_\ell, \]
where
\[ D_{k \ell} = \begin{cases} c_k - c_k a'_k \left( \sum_{i \in S} c_i a_i a'_i \right)^{-1} a_k c_k, & k = \ell, \\ c_k a'_k \left( \sum_{k \in S} c_k a_k a'_k \right)^{-1} a_\ell c_\ell, & k \neq \ell. \end{cases} \]

The five definitions of the \( c_k \)'s are denoted \( c_{k1}, c_{k2}, c_{k3}, c_{k4}, \) and \( c_{k5} \), and allow to define five variance estimators by replacing in expression (12) \( c_k \) by, respectively, \( c_{k1}, c_{k2}, c_{k3}, c_{k4}, \) and \( c_{k5} \).

(1) The first estimator is obtained by taking \( c_{k1} = (1 - \pi_k) \).
(2) The second estimator is obtained by applying a correction for loss of degrees of freedom
\[ c_{k2} = (1 - \pi_k) \frac{n}{n - p}. \]
This correction for the loss of degrees of freedom gives the unbiased estimator in simple random sampling with fixed sample size.
(3) The third estimator derives from the fact that the diagonal elements of the true matrix \( \Delta_{k \ell}/\pi_{k \ell} \) are always known and are equal to \( 1 - \pi_k \). Thus we can use
\[ c_{k3} = (1 - \pi_k) \frac{\sum_{k \in S} (1 - \pi_k)}{\sum_{k \in S} D_{kk}}. \]
(4) The fourth estimator can be derived from \( b_{k4} \) obtained by solving equation system (10),
\[ c_{k4} = \frac{b_{k4}}{\pi_k} \frac{n}{n - p} \frac{N - p}{N}. \]
(5) Finally, the fifth estimator derives from the fact that the diagonal elements \( D_{kk} \) are known. The \( c_{k5} \) are constructed in such a way that
\[ 1 - \pi_k = D_{kk}, \quad k \in U \] (13)
or in other words that
\[ 1 - \pi_k = c_k - c_k a'_k \left( \sum_{i \in S} c_i a_i a'_i \right)^{-1} a_k c_k, \quad k \in U. \]
This fifth approximation is the only one that provides the exact unbiased variance estimator for stratification. A necessary condition in order that a solution exists for equation system (13), is that

$$\max_k \frac{1 - \pi_k}{\sum_{\ell \in S}(1 - \pi_\ell)} < \frac{1}{2}.$$ 

7. Conclusion

We have shown that the variance of the Horvitz–Thompson estimator under balanced sampling can be approximated and estimated with a residual technique. Balanced sampling can be viewed as a calibration (Huang and Fuller, 1978; Deville and Särndal, 1992) at design stage. Like for calibration, the variance under balanced sampling can be approximated as a variance of residuals. Numerical results support our findings.

Acknowledgements

The authors are grateful to Jean Dumais and David Leblanc for their interesting comments on a previous version of this paper, and to Carl Särndal for his great encouragement.

Appendix A. Technical theorem

We need a following technical theorem in order to prove Theorem 1.

**Theorem A.1.** Let $m_0$ be a probability measure on $\mathbb{R}^N$ with a compact support $K$, $C$ the convex closure of $K$, and $\overset{\circ}{C}$ the interior of $C$ assumed to be non-empty. Let $m_\lambda$, $\lambda \in \mathbb{R}^N$ the exponential family of probability measures defined by

$$m_\lambda(dx) = \exp[\lambda'x - \mu(\lambda)]m_0(dx),$$

where

$$\exp \mu(\lambda) = \int \exp(\lambda'x)m_0(dx).$$

The expectation of $m_\lambda(dx)$ is the vector $\pi = \mu'(\lambda)$ and the variance matrix is $\mu''(\lambda)$. The mapping $\lambda \rightarrow \pi = \mu'(\lambda)$ is a $C^\infty$ diffeomorphism (i.e. a one-to-one and indefinitely differentiable) from $\mathbb{R}^N$ onto $\overset{\circ}{C}$.

**Proof.** The first statement is a standard fact. Moreover the fact that $\mu''(\lambda)$ is of full rank for every $\lambda$ implies that the mapping is injective. Differentiability for all orders is obvious. It remains to prove that it is onto. For this purpose we need a following Lemma (which is actually the proof for the case $N = 1$).
**Lemma A.1.** Let \( m_0^1 \) be a probability measure that has \([0, 1]\) for convex closure of its support, and \( m_\lambda^1 \) the probability measure

\[
\exp[-\lambda x - \mu(\lambda)]m_0^1(dx) \quad (\lambda, x \in \mathbb{R}).
\]

Then \( \int x \, dm_\lambda^1(x) \) is a continuous decreasing function with limit equal to 0 when \( \lambda \) tends to infinity.

**Proof.** The function is obviously continuous and decreasing. Now let \( \varepsilon > 0 \) arbitrary small,

\[
p_\lambda^0 = m_\lambda^1 \left( \left[ 0, \frac{\varepsilon}{4} \right] \right), \quad p_\lambda^1 = m_\lambda^1 \left( \left[ \frac{\varepsilon}{2}, 1 \right] \right).
\]

As

\[
\frac{p_\lambda^0}{p_\lambda^1} \geq \frac{p_0^0}{p_0^1} \exp \frac{\lambda \varepsilon}{4},
\]

\( p_\lambda^1 \) tends to 0 when \( \lambda \) increases. We conclude by using the trivial majoration

\[
\int x \, dm_\lambda^1(x) \leq \varepsilon/2 + p_\lambda^1.
\]

Let now \( u \) be any unit vector in \( \mathbb{R}^N \) (with the standard metrics) and \( t(u) > 0 \) such that

\[
f_u(x) = t(u)u'(x - \pi_0) = 1, \quad \left( \pi_0 = \int x \, dm_0(x) = \mu'(0) \right)
\]

is the equation of a tangent hyperplan to \( C \). As \( C \) is compact, \( t(u) \) is a bounded function on the unit sphere of \( \mathbb{R}^N \) and \( C = \bigcap_u \{ f_u(x) \leq 1 \} \). Consider \( C_\varepsilon = \bigcap_u \{ f_u(x) \leq 1 - \varepsilon \} \), the homothetic of \( C \) by the homothety centered at \( \pi_0 \) (which belongs always to \( C_\varepsilon \)) that has ratio \( 1 - \varepsilon \). Let \( B_r \) the ball of radius \( r \) in \( \mathbb{R}^N \) and \( D_r \) its border, \( C(r) = \mu'(B_r), \tilde{C}_r = \mu'(D_r) \) the border of \( C(r) \). This set delimits two regions in \( \tilde{C} \), the interior to which belongs \( \pi_0 \) and the exterior. As \( \mu' \) restrained to \( B_r \) define a homotopy, every point of the interior is also in \( C(r) \). It remains to show that for \( \varepsilon \) given, we can find \( r \) such that \( C_\varepsilon \subset C(r) \), or, which is the same, that \( \tilde{C}(r) \) is outside of \( C_\varepsilon \). Note that \( f_u \) maps the probability measure \( m_0(dx) \) on a real probability measure \( m_0^* (d\xi) \) which has support for extreme points \(-t(-\lambda)/t(\lambda) \) and 1. For \( \lambda = \varepsilon u, m_\lambda^*(d\xi) \) is mapped to the probability measure

\[
m_\varepsilon^*(d\xi) = \exp[\varepsilon \xi - \mu(\varepsilon u)] \, dm_0^*(\xi).
\]

We have

\[
f_u(\varepsilon u) = \int \exp[\varepsilon \xi - \mu(\varepsilon u)] \, dm_0^*(\xi).
\]

From Lemma A.1, we get the existence of \( \varepsilon(u) \) such that \( f_u(\varepsilon u) = 1 - \varepsilon/2 \) and \( f_u(\varepsilon(u)) > 1 - \varepsilon/2, \) if \( \varepsilon > \varepsilon(u) \). All the \( \varepsilon(u) \) have a supremum \( r(\varepsilon) \) and \( \mu^*(D_r(\varepsilon)) = \tilde{C}(r(\varepsilon)) \) is outside of \( C_\varepsilon \), which completes the proof. \( \square \)
Remark. When $K$ is a finite set and $m_0$ the uniform measure on $K$, Theorem A.1 follows easily from the fact that every point $\pi$ in $C$ is a convex combination of the extreme points of $K$ (existence of a probability measure supported by $K$ having $\pi$ for mean) and from the existence of a maximum entropy probability on $K$ with mean $\pi$. This probability gives to the points $x$ of $K$ masses proportional to $\exp(\lambda'x)$ for some $\lambda$.

Appendix B. Proof of Theorem 1

(i) Let

$$\Omega_X = \left\{ s \in \Omega \left| \sum_{k \in s} \frac{x_k}{\pi_k} = A_s = X = A\pi \right. \right\}.$$

This set is the set of extreme points of the convex compact $(\pi + \text{Ker } A) \cap C$ and lies in a linear subspace of dimension $N - p$. From Theorem A.1 of Appendix A (or only the remark at the end of Appendix A), there exists a unique vector $\lambda_0$ in $\text{Ker } A$ (satisfying $A\lambda_0 = 0$) such that with

$$p_X(s) = \frac{\exp \lambda' s}{\sum_{s \in \Omega_X} \exp \lambda' s},$$

we have

$$\pi_k = \sum_{s \in \Omega_X} sp_X(s) = \sum_{s \ni k \in \Omega_X} p(s).$$

This plan is the maximum entropy sampling design with support $\Omega_X$ and inclusion probabilities $\pi_k$.

(ii) Observe that a Poisson sampling design can be defined by

$$\tilde{p}(s) = \frac{\exp \lambda_0' s}{\sum_{s \in \Omega} \exp \lambda_0' s}$$

and that $p_X(s)$ is $\tilde{p}(s)$ conditional on $s \in \Omega_X$. Let $\mathcal{A} = \{As|s \in \Omega\}$ and for $c \in \mathcal{A}$, $\Omega_a = \{s|As = c\}$ and

$$q(c) = \sum_{s \in \Omega_a} \tilde{p}(s).$$

Observe that the convex closure of $\mathcal{A}$ (in $\mathbb{R}^p$) is exactly $A(C) = \{Ax|x \in C\}$, and that $q(c), c \in \mathcal{A}'$, define a probability measure on $\mathcal{A}$. We can rewrite

$$\tilde{p}(s) = q(As)\tilde{p}(s|As = c),$$

where $s \in \Omega_a$, and

$$\tilde{p}(s|As = c) = p_a(s) = \frac{\exp \lambda_0' s}{\sum_{s \in \Omega_a} \exp \lambda_0' s}. \quad (B.1)$$
(iii) By Theorem A.1 of Appendix A, we get that for any \( c \) lying in the interior of the convex set \( A(C) \), for \( c = X \) for instance, since \( X = \Lambda \pi \) and \( \pi \) is in the interior of \( C \), there exists a uniquely defined \( v \in \mathbb{R}^p \) such that
\[
c = \sum_{x \in A} x \exp[v'x - \mu_A(v)] q(x),
\]
where
\[
\mu_A(v) = \sum_{c \in \mathcal{A}} q(c) \exp(v'c).
\]

(iv) Let
\[
\tilde{p}^*(s) = \exp[v'As - \mu_A(v)c] q(As) p_{As}(s)
\]
coming from the probability \( q \) on \( \mathcal{A} \) used in (B.2) and the family of conditional probabilities (B.1). We can rewrite
\[
\tilde{p}^*(s) = \frac{\exp[(\lambda_0 + A'v)s]}{\sum_{s \in \Omega} \exp[\lambda_0's + \mu_A(v)]}.
\]
Observe that \( v \rightarrow \lambda_1 = A'v \) is a bijection of \( \mathbb{R}^p \) onto \( \text{Im} \ A' \), the orthogonal subspace of \( \text{Ker} \ A \) (for the standard metrics on \( \mathbb{R}^N \)) and \( \lambda = \lambda_0 + \lambda_1 \) is a uniquely defined vector of \( \mathbb{R}^N \). Therefore
\[
\tilde{p}^*(s) = \frac{\exp(\lambda s)}{\sum_{s \in \Omega} \exp(\lambda s)}
\]
is a Poisson sampling design uniquely defined such that
\[
\tilde{p}^*(s) \text{ conditional to } s \in \Omega_a \text{ is } p_X(s) \text{ and }
\]
\[
E_{\tilde{p}^*} \left( \sum_{k \in S} \frac{x_k}{\pi_k} \right) = X.
\]

**Remark B.1.** This design has the interest of concentrating the probability on the vicinity of \( \Omega_X \), unlike to any choice of \( c \neq X \).

**Remark B.2.** A nice purely algebraic way to see the mean and variance property of \( \tilde{p} \) is the following:
\[
\tilde{p}_k = \sum_{s \in \Omega} \tilde{p}^*(s) = \exp(\lambda_k) \sum_{s \in \Omega} \exp(\lambda'_{s}) = \exp(\lambda_k)(1 - \tilde{p}_k).
\]
The mean for \( \tilde{p}^* \) (from the first statement of Theorem A.1 in Appendix A) is computed from
\[
\exp \mu(\lambda) = \sum_{s \in \Omega} \exp(\lambda'_{s})
\]
which gives
\[
\exp \mu(\lambda) \frac{d\mu}{d\lambda} = \begin{bmatrix} \vdots \end{bmatrix} \sum_{s \in k} \exp(\lambda's)
\]
and therefore
\[
\frac{d\mu}{d\lambda} = \begin{bmatrix} \vdots \end{bmatrix} \tilde{\pi}_k \begin{bmatrix} \vdots \end{bmatrix}.
\]
The variance operator for \(\tilde{\rho}^*\) is
\[
\frac{d^2\mu}{d\lambda^2} = \left[ \frac{d\tilde{\pi}_k}{d\lambda_k} \right] = \text{diag}(\tilde{\pi}_k(1 - \tilde{\pi}_k)).
\]

Appendix C. Elements for justifying the approximated variance in the non-exact case

We seek an approximation concerning the flight phase, assuming that the landing phase consists essentially of a kind of rounding. We have to set up a quite complicated construction.

C.1. \(p\)-faces

Let \(U^*\) be any subset of \(p\) co-ordinates amongst \([0,1]\). A \(p\)-face \(f\) is a set indexed by a partition \((U^0, U^1, U^*)\) of \([0,1]\) such that \(x_k = 0\), if \(k \in U^0\), \(x_k = 1\), if \(k \in U^1\), \(x_k \in [0,1]\), if \(k \in U^*\). Let \(C_p\) be the reunion of all the \(p\)-faces. This set can be canonically equipped with the probability measure
\[
m = \frac{1}{2^{N-p} \binom{N}{p}} \sum_f m_f,
\]
where \(m_f\) is the \(p\)-dimensional Lebesgue measure on \(\mathbb{R}^N\).

By simplicity, assume that all square submatrices \(A_{U^*} = [a_k, k \in U^*]\) of \(A\) have rank \(p\). This is almost always the case if we can consider the \(a_k\) as drawn independently from some continuous multivariate distribution. The set \(\Omega_\alpha\) of extreme points of \(C \cap \{Ax = c\}\) is exactly \(C_p \cap \{Ax = c\}\). In particular, \(A(C_p) = A(C) = \mathcal{A}\) (take \(\pi \in C\); \(\Omega_{A\pi}\) is not empty). Every point \(c\) of \(\mathcal{A}\) determines the convex polyhedron \(C \cap \{Ax = c\}\) and \(\Omega_\alpha\), its set of extreme points.
C.2. A family of maximum entropy probabilities

Like in Appendix B, we start with $q_{LFX}$. For simplicity, at once, assume that $X$ is an ordinary point in $\mathcal{A}$ in this sense that $q_{LFX} = q_{LFp} = \overline{7SZ} + C_p$ (with $\overline{7SZ} + C_p = \bigcup_{q < p} C_q$). There exists a uniquely defined vector $\lambda_0 \in \text{Ker} A$ such that the probability defined on $\Omega_X$ by

$$p_X(\pi^*) = \frac{\exp[\lambda_0' \pi^* - \mu_X(\lambda_0)]}{|\Omega_X|}$$

has for mean $\pi$ (given). This is, as is easily seen, the maximum entropy probability measure on $q_{LFX}$.

Define now on $C_p$ the probability measure

$$\tilde{p}^* (\lambda' \pi^*) = \exp[\lambda_0' \pi^* - \mu(\lambda_0)] \, dm(\pi^*)$$

with

$$\mu(\lambda_0) = \int_{C_p} \exp(\lambda_0' \pi^*) \, dm(\pi^*).$$

For every $c$ in the set of ordinary points in $\mathcal{A}$, we can define a maximum entropy probability on $\Omega_a$

$$\tilde{p}_a^* (\pi^*) = \frac{\exp[\lambda_0' \pi^* - \mu_a(\lambda_0)]}{|\Omega_a|}.$$

Let $\pi^*_a$ be the mean on $\tilde{p}_a^*$ and $V_a$ its variance operator. Let $p^d_0$ be the probability measure $\tilde{p}^*$ ‘projected’ on $\mathbb{R}^p$ by $A$:

$$p^d_0 (dc) = \tilde{p}^*(A^{-1}(da)).$$

The support of $p^d_0$ is $\mathcal{A}$ which is a convex set (a zonoid in the terminology of Ziegler (1998)). Moreover $p^d_0$ has density $\exp(\mu_a(\lambda_0) - \mu(\lambda_0))$ with respect to $m^d$, ‘projection’ of $m$ and $m^d$ can be written as

$$m^d(dc) = m(A^{-1}(dc)) = \sum_f \det(A_{U^*(f)})^{-1} \, dc,$$

where the sum is over all the $p$ faces $f$ such that $c \in A(f)$. It is clear that we have the desegregation

$$\tilde{p}^* = \sum_{\mathcal{A}} \tilde{p}_a^* A(da)$$

The family $\tilde{p}_a^*$ varies continuously when $c$ varies in every open region on $\mathcal{A}$ on which no point of $\overline{7SZ} + C_p$ is projected. This set of ‘extraordinary’ points has a measure 0 for $m^d$ and $p^d_0$.

C.3. Continuity problems

For $\tilde{p}_a^*$, we do not need to define $\tilde{p}_a^*$ when $c$ is an ‘extraordinary’ point. However, from a statistical point of view, it is necessary to have a reasonable coherent definition. Let $c_0$ be ‘extraordinary’ in $\mathcal{A}$. This point is the image by $A$ of some point $\pi_0^* \in C_q - \overline{C_q}$.
with \( q < p \) and belongs to a ‘segment’ of dimension \( q \) in \( \mathcal{A} \). This segment is adjacent to

\[
\begin{pmatrix}
N - p + q \\
p - q
\end{pmatrix}
\]
p-faces. For instance, if \( \pi_0^* \in C_{p-1} - \tilde{C}_{p-1} \), it belongs to a hyperplane delimiting two regions in \( \mathbb{R}^p \) and there are \( N - p + 1 \) \( p \)-faces adjacent to \( \pi_0^* \). When \( \mathbf{c} \) varies on some lines in \( \mathcal{A} \) crossing this hyperplane at \( \mathbf{c}_0 \), the number of points \( \Omega_a \) is a number \( r \leq N - p + 1 \) before the crossing and \( N - p + 1 - r \) after the crossing. The most ‘continuous’ way to define a weight at \( \pi_0^* \) (and \( \mathbf{c}_0 \)) is to put \( w(\pi_0^*) = (N - p + 1)/2 \). By re-iterating the same argument, we obtain the weight

\[
w(\pi^*) = \left( \begin{array}{c} N - p + q \\ p - q \end{array} \right) 2^{-(p-q)}
\]

(C.3)
to a point \( \pi^* \) in \( C_q - \tilde{C}_q \), \( 0 \leq q \leq p \).

If \( \mathbf{X} \) is an extraordinary point, we extend the definition given in (C.1) of \( p_X \):

\[
p_X(\pi^*) = \frac{\exp[\lambda_0^* \mu_X - \mu_X(\lambda_0)]w(\pi^*)}{\sum_{\Omega_x} w(\pi^*)}.
\]

With this construction extended to \( p_a \), \( \mathbf{c} \) extraordinary, we get a family of probabilities on the \( q_L^a \) such that \( p_{a_0} \) is always a mean between the limits of \( p_c \) when \( \mathbf{c} \) tends to \( \mathbf{c}_0 \) coming from different directions.

In some cases, we achieve a complete continuity, for instance when \( \mathbf{A} = (1, \ldots, 1) \) of rank 1, which occurs with the fixed sample size constraint, and \( \mathbf{c} \) varies from 0 to \( N \) in \( \mathbb{R} \). As a consequence, \( \pi_a^* \) and \( \mathbf{V}_a \) are continuous functions of \( \mathbf{c} \).

C.4. Exponential families on \( (C_p, m) \)

Again, the developments in this section are similar to Appendix B, although technically a bit more involved. As \( \mathcal{A} \) is convex, compact in \( \mathbb{R}^p \) and is the support of \( p^A_0 \), for every \( \mathbf{c} \in \mathcal{A} \) (interior of \( \mathcal{A} \),) there exists a uniformly defined vector \( \mathbf{v}_a \in \mathbb{R}^p \) such that

\[
\mathbf{c} = \int_{\mathcal{A}} \mathbf{x} \exp(\lambda_0^* \mathbf{x} - \mu(\lambda_0)) \, d\rho_0^A(\mathbf{x}) = E_{p^A_0}(\mathbf{x}).
\]

In particular, there is a uniquely defined value \( \mathbf{v} = \mathbf{v}_X \) such that \( \mathbf{X} = E_{p^*_X}(\mathbf{x}) \). Consider now that exponential family in \( C_p \) indexed by \( \lambda \in \mathbb{R}^N \).

\[
\tilde{p}_X(\mathbf{d}\pi^*) = \exp(\lambda^* \mathbf{v}^* - \mu(\lambda)) \, d\pi^*.
\]

As \( \lambda \) has a unique decomposition \( \lambda = \lambda_0 + \lambda_1 \) with \( \lambda_0 \in \text{Ker} \mathbf{A} \) and \( \lambda_1 = \mathbf{A}' \mathbf{v} \) (\( \mathbf{v} \in \mathbb{R}^p \), we have just proved (as in Theorem 1) that there exists a uniquely defined \( \lambda \in \mathbb{R}^N \) such that \( E_{p^*_X}(\mathbf{A}\pi^*) = \mathbf{X} \), and \( \tilde{p}_X(\mathbf{A}\pi^*|\mathbf{A}\pi^* = \mathbf{X}) = p_X(\pi^*) \). Moreover, we have
the desegregation

\[ \tilde{p}_\lambda^* = \int_{\mathcal{A}} p_a \, d\tilde{p}_\lambda^*(c). \]

We also have the standard decomposition for the variance operator \( V \):

\[ V = V_I + V_B \]

with

\[ V_I = \int_{\mathcal{A}} \nu_a \, d\nu_I^*(c), \]

and

\[ V_B = \int_{\mathcal{A}} [\pi_a^* - E(\pi_a^*)][\pi_a^* - E(\pi_a^*)]' \, d\nu_I^*(c). \]

Operator \( V_I \) has for image \( \text{Ker} A \) because it is already the case for every \( \nu_a \). Its kernel is the orthogonal supplement of \( \text{Ker} A \) in the metric defined by \( V \), that is if \( P = I - VA'(AVA')A \) is this projector, \( V_I = P'VP \).

C.5. Variance approximation

We anticipate that \( V_I \) is a good approximation for \( V_X \). We rely on three other approximations which are very plausible for \( N \) large enough (which we can prove completely for the fixed sample size case).

(i) First approximation: \( \nu_a \) varies continuously with \( c \) when \( c \) varies in an open zone of \( \mathcal{A} \). When \( c \) crosses a border at a point \( c_0 \in C_q, q < p \), the discontinuity on \( \nu_a \) has the order of magnitude of

\[ \left( \begin{array}{c} N \\ p - q \end{array} \right) \]

number of \( p \) faces projecting on \( c_0 \). The denominator of this ratio is not easy to estimate (see Ziegler, 1998, Chapters 8 and 9 and the bibliography therein) but if \( c_0 \) is ‘central’ enough, it is very large. Remark that, with our convention for discontinuity point in (C.3), \( \nu_a \) is continuous in the fixed sample size constraint case when \( c \) varies in \( \mathbb{R} \) from 0 to \( N \). A formal conclusion of this informal conclusion is that we should be correct when writing that for \( \varepsilon > 0 \) given, there exists some \( r > 0 \) such that \( \|V_X - \nu_a\| < \varepsilon \) if \( \|X - c\| < r \) (standard norm in \( \mathbb{R}^p \) and an operator norm for the first inequality).

(ii) Second approximation: As the expectation of \( \nu_I^* \) is \( X \), we may think that the probability concentrates in a neighborhood of \( X \) when \( N \) is large. We could invoke a tendency to a normal distribution or a similar argument. For the fixed sample size constraint, \( |s| = n \), both \( \lambda = \lambda, c = a \) are scalar. It is then easy to see that the density of \( \nu_I^* \) on the interval \( [m - 1, m], m = 1, \ldots, N, \) is proportional to \( \left( \begin{array}{c} N \\ m \end{array} \right) \) \( \exp \lambda a \) and that \( \exp \lambda \) is nearly equal to \( n/(N - n) \). In this case, our assertion is easy to satisfy.
Formally, we would write that for \( N \) large
\[
\rho_{\epsilon}^A(\{c; ||X - c||\}) > 1 - \epsilon.
\]

Putting together the assumptions in (i) and (ii), we get that for \( N \) large and \( X \) sufficiently ‘central’ in \( \mathcal{A} \), \( V_L \) is a close approximation of \( V_X \).

(iii) **Third approximation:** Concerning \( \tilde{p}_L^* \) (and therefore \( V \)), for each co-ordinate \( \lambda_k \) of \( \lambda \), set
\[
\tilde{\pi}_k = \frac{\exp \lambda_k}{1 + \exp \lambda_k}.
\]
The density \( d \tilde{p}_L^*/dm \) is proportional to
\[
\prod_{k \in U} \tilde{\pi}_k \left(1 - \tilde{\pi}_k \right)^{1 - \tilde{\pi}_k}.
\]

If \( \pi^* = s \) is a sample (a point that has integer co-ordinates), we find exactly the probability \( \tilde{p}^*(s) \) of the Poisson sampling design with inclusion probabilities \( \tilde{\pi}_k \). It remains to see that the probability \( \tilde{p}_L^*(d\pi^*) \) on \( C_p \) is well approximated by
\[
\sum_s \tilde{p}^*(s) \delta_s,
\]
where \( \delta_s \) is the unit Dirac mass at \( s \). It is easy to see that it is true and in particular, that \( V \) can be approximated by \( \tilde{\Lambda} = \text{diag}(\tilde{\pi}_k (1 - \tilde{\pi}_k)) \), the variance operator of the Poisson sampling design.

As it is seen in Section 5, this heuristic reasoning is completely confirmed by the numerical study.

**Appendix D. Proof of Theorem 2**

The problem consists of finding some numbers \( \omega_k > 0 \) of vector \( \omega \) of \( \mathbb{R}^N \) with \( \sum_{k=1}^N \omega_k = 1 \), and a constant \( \Omega \) such that
\[
d \rho_k = d \Omega (\omega_k - \omega_k^2), \tag{D.1}
\]
with \( d = \sum_{k=1}^N \pi_k (1 - \pi_k) \), and
\[
\rho_k = \frac{\pi_k (1 - \pi_k)}{d}.
\]

By summing the equations we find that
\[
\Omega = \frac{1}{1 - \sum_{k=1}^N \omega_k^2} = \frac{1}{1 - \Omega_2}.
\]
When $N = 3$, after some algebra, one can find the algebraic solution

$$\omega_k = 1 - \frac{2\rho_k(1 - 2\rho_k)}{1 - 2\sum_{i=1}^{3} \rho_i^2}$$

and a closer look shows the solution is acceptable only if $\max \rho_k < \frac{1}{2}$.

In the general case, we shall prove that the mapping

$$F(\omega) = \begin{bmatrix}
\vdots \\
\omega_k - \omega_k^2 \\
\frac{1}{1 - \Omega_2} \\
\vdots 
\end{bmatrix}$$

is a bijection from the open set

$$D = \left\{ \omega_k \ \bigg| \sum_{k=1}^{N} \omega_k = 1, \omega_k > 0 \right\}$$

onto the open set

$$E = \left\{ \rho_k \ \bigg| \sum_{k=1}^{N} \rho_k = 1, \omega_k < \frac{1}{2} \right\}.$$

The proof is completed in three steps: (1) $F$ is injective; (2) $F$ maps $D$ into $E$; (3) $F$ maps $D$ onto $E$.

**Step 1: $F$ is injective.** We have

$$(1 - \Omega_2) \frac{dF}{d\omega} = \text{diag} (1 - 2\omega_k) + 2F(\omega)\omega'.$$

$F$ is injective, if $dF/d\omega$ is off full rank $N - 1$ on the plane $\sum_{k=1}^{N} u_k = 0$ for every $\omega \in D$. Therefore, we have to prove that we cannot find numbers $u_k$ not simultaneously equal to 0 satisfying $\sum u_k = 0$ and for every $k$:

$$(1 - 2\omega_k)u_k + 2 \frac{\omega_k - \omega_k^2}{1 - \Omega_2} \sum_{\ell} \omega_{\ell}u_{\ell} = 0. \quad (D.2)$$

1. $\sum_{\ell} \omega_{\ell}u_{\ell} = 0$ is impossible because:
   (a) If $\omega_k = \frac{1}{2}$ for all $k$, (D.2) gives $u_k = 0$.
   (b) At most one $\omega_k = \frac{1}{2}$ say $\omega_1$. All the $u_k = 0$ for $k \geq 2$ because of (D.2).
   Moreover, $u_1$ is also equal to 0 because $\sum u_k = 0$.

2. The $u_k$ are defined up to an arbitrary multiplier and we can normalize by

$$\sum_k \omega_k u_k = 1.$$

Then
   (a) If some $\omega_k = \frac{1}{2}$, there is no solution for (D.2).
   (b) If all $\omega_k < 1/2$, all $u_k > 0$ and $\sum_k \omega_k u_k \neq 0$.  

\(2\)
(c) One of the \( \omega_k \) say \( \omega_1 > \frac{1}{2} \) and therefore \( u_1 < 0 \) and \( u_k > 0 \), for all the other \( k \). Let \( \omega_+ = \max_{k \geq 2} \omega_k \), \( \omega_+ < 1 - \omega_1 < \frac{1}{2} \). Moreover,
\[
\sum_{k=1}^{N} \omega_k u_k = -\omega_1 |u_1| + \sum_{k=2}^{N} \omega_k u_k \leq -\omega_1 |u_1| + \omega_+ (1 + |u_1|) \leq \omega_+ - (\omega_1 - \omega_+) |u_1| < 1/2,
\]
which concludes Step 1.

**Step 2:** \( \mathcal{F} \) maps \( D \) in \( E \). We prove for instance that \( \rho_1 < \frac{1}{2} \). Set \( \omega_1 = (1 - t) \) and for any \( k \geq 2 \), \( \omega_k = tv_k \left( \sum_{k=2}^{N} v_k = 1, v_k > 0 \right) \). Then
\[
\rho_1 = \frac{t(1-t)}{1-(1-t)^2-t^2 \sigma} = \frac{1}{2} - \frac{1}{2} \times \frac{t(1-\sigma)}{2-t(1+\sigma)},
\]
where
\[
\sigma = \sum_{k=2}^{N} v_k^2 < 1.
\]
Therefore \( \rho_1 < \frac{1}{2} \) but \( \lim_{t \to 0} \rho_1 = \frac{1}{2} \). For others \( k \),
\[
\rho_k = \frac{v_k}{2} + \frac{1}{2} \times \frac{tv_k(1+\sigma - 2v_k)}{2-t(1+\sigma)}
\]
and thus \( \lim_{t \to 0} \rho_k = v_k/2, k \geq 2 \).

**Step 3:** \( \mathcal{F} \) maps \( D \) onto \( E \). We follow a similar method as in the proof of Theorem A.1 of Appendix A, and give only a sketch.

(1) Let
\[
D_r = \{ \omega : \min \omega_k \geq r \text{ and } \max \omega_k \leq 1 - r \}
\]
and \( \tilde{D}_r \), the border of this set. Those sets form an increasing family (when \( r \) decreases) of compact in \( D \) of which the union is \( D \).

(2) Let
\[
E_\varepsilon = \left\{ c : \max \rho_k \leq \frac{1}{2} - \varepsilon \text{ and } \min \rho_k \geq \varepsilon \right\}.
\]
Using the equations of Step 2, one can show that for all \( \varepsilon \) there exists an \( r \) such that \( F(\tilde{D}_r) \) is outside \( E_\varepsilon \); like in the proof of Theorem A.1 in Appendix A, we conclude that \( E \) is covered.

**Remark on Theorem 2.** Theorem 2 is also related to a very classical sampling problem. Suppose that a sample of size \( n = 2 \) is selected with replacement using unequal probabilities \( p_k \) for each drawn, where \( \sum_{k \in U} p_k = 1 \). The rejective sampling design
consists of selecting the first sample that has two distinct units. Then the probability
to select the sample \( s = \{i, j\} \) is given by

\[
p(s) = \pi_{ij} = \frac{2 p_i p_j}{\sum_{k \in U} \sum_{\ell \neq k} p_k p_\ell} = \frac{2 p_i p_j}{1 - \sum_{k \in U} p_k^2}.
\]

Since \( n = 2 \) the first-order inclusion probabilities are given by

\[
\pi_i = \sum_{j \neq i} \pi_{ij} = \frac{2 p_i (1 - p_i)}{1 - \sum_{k \in U} p_k^2}. \tag{D.3}
\]

If the \( \pi_i \) are given, and the aim is the determination after the \( p_i \), we have to solve
equation system (D.3), which is exactly the same as (D.1). Note that since \( \sum_i \pi_i = 2 \),
Theorem 2 shows that a solution always exists.
