VECTOR-BORNE DISEASES, SURVEILLANCE, PREVENTION

CORALIE HERRMANN AND LISE GERN1

Institute of Biology, Laboratory of Eco-Epidemiology of Parasites, University of Neuchâtel, Emile Argand 11, Case postale 158, 2009 Neuchâtel, Switzerland

ABSTRACT To determine whether *Borrelia burgdorferi* sensu lato (s.l.) influences tick survival under thermohygrometric stress, *Ixodes ricinus* (L.) (Acari: Ixodidae) questing ticks were tested under various relative humidities (13, 32, 51.5, 61, and 89% RH) at two different temperatures (12.5 and 25°C) and investigated for *Borrelia* infection. Survival rate of females was highest (77.6%), followed by males (51.6%), and nymphs (43.2%). The thermohygrometric factor that most importantly determined survival was saturation deficit (SD). As SD increased, tick survival rate decreased in all stages. Among the 1,500 ticks tested for *B. burgdorferi* s.l., 34.8% (*n* = 522) were infected. Adult infection rate (39.6%) was higher than that of nymphs (25.5%). Infection load in real-time polymerase chain reaction ranged from 1 to 1.2 million spirochetes per tick. *B. afzelii* (39.7%), *B. burgdorferi* sensu stricto (12.1%), *B. garinii* (37.9%), *B. myzometa* (3.6%), and *B. valaisiana* (23.8%) were recorded. *B. garinii* infected significantly less nymphs than adults whereas *B. afzelii* displayed the opposite trend. Survival rate of nymphal and adult *I. ricinus* was significantly enhanced by infection by *B. burgdorferi* s.l. (*χ²*: nymph, *P* = 0.005; adult, *P* = 0.021). In adults, a negative effect of infection on tick survival was observed when spirochete load overcame a threshold estimated at 160,000 spirochetes per tick but not in nymphs. Moreover, ticks infected by *B. afzelii* survived better than other ticks (infected by other genospecies or not). The results here indicate that infection by *B. burgdorferi* s.l. and more specifically infection by *B. afzelii*, confers survival advantages to *I. ricinus* under challenging thermohygrometric conditions.

KEY WORDS Lyme disease, *Ixodes ricinus*, climate change, tick survival, Switzerland

The hard-bodied tick *Ixodes ricinus* (L.) (Acari: Ixodidae) is the main vector of *Borrelia burgdorferi* sensu lato (s.l.), the etiological agent of the most common tick-borne disease in Europe, Lyme borreliosis. Ten *Borrelia* genospecies have been described in *I. ricinus* in Europe: *B. afzelii*, *B. baculovirus*, *B. bissetii*, *B. burgdorferi* sensu stricto (s.s.), *B. carolinensis*, *B. garinii*, *B. lusitaniae*, *B. spielmanii*, *B. valaisiana* as well as a *Borrelia* species related to relapsing fever spirochetes, *B. myzometa* (Rauter and Hartung 2005, Margos et al. 2009, Gern et al. 2010, Cotte et al. 2010). Both *B. burgdorferi* s.l. and ticks of the *I. ricinus* complex have been thoroughly studied on their own, but knowledge on the influence of infection by *Borrelia* on ticks remains scarce.

The effect of infection by *B. burgdorferi* s.l. on the behavior of *Ixodes* ticks has been documented. Hence, it was observed that infection by *B. burgdorferi* s.l. in *I. persulcatus* and *I. ricinus* ticks reduced motor activity of both adult and immature infected individuals compared with uninfected ticks (Alekseev et al. 2000). Moreover, Lefcourt and Durden (1996) reported that infection by *B. burgdorferi* s.l. influenced *I. scapularis* phototaxis, activity and questing height. Infected adults were less able to overcome physical obstacles, avoided vertical surfaces, were less active and quested at lower heights, whereas infected nymphs showed increased phototaxis and attraction to vertical surfaces. It also was observed that infection by *B. burgdorferi* s.l. increased questing activity in *Ixodes persulcatus* Schulze (Naumov 1999 cited by Uspensky et al. 2006) and host-finding efficacy in adult *I. ricinus* (Faulde and Robbins 2008).

In contrast, reports on the effect of parasites on the physiology of ticks are rare. Mather et al. (1993) observed a higher survival rate of *Ixodes scapularis* Say nymphs infected by *B. burgdorferi* s.l. than uninfected nymphs after habitat burning, suggesting that infection by *B. burgdorferi* s.l. makes ticks more resistant to heat and desiccation. Furthermore, in 1998 in Neuchâtel, Switzerland, a lower density of questing *I. ricinus* ticks was observed due to high desiccating climatic conditions (Perret et al. 2000) and an unexpectedly high percentage of nymphs harboring high numbers of *B. burgdorferi* s.l. was recorded compared with the previous and following

1 Corresponding author, e-mail: lise.gern@unine.ch
years (L.G., unpublished data). In addition, Nau
mov (2003) (cited by Uspensky et al. 2006) noted that there was a trend toward an increase in the longevity of adult *I. ricinus* and *I. persulcatus* in-
fected by *B. burgdorferi* s.l. spirochetes.

Similarly to other terrestrial arthropods, the biggest challenge for ticks is to maintain water balance while living in a relatively dry environment. This is even more crucial for *I. ricinus* survival because this tick is exceptionally sensitive to temperature and humidity compared with other ticks (Knüllé and Rudolph 1982, Sonenshine 1991). Hence, combined with temperature, humidity is the most important limiting factor in *I. ricinus* survival and activity because the different developmental stages are known to display little resistance to desiccation (MacLeod 1935, Lees 1946, Aeschlimann 1972). In fact, relative humidity needs to be >70–80% to allow questing tick activity and sur-
vival (MacLeod 1935). More precisely, saturation defect (SD), a measure of the drying power of the at-
mosphere depending on both temperature and relative humidity (Randolph and Storey 1999), limits duration of questing (Perret et al. 2003, 2004) and survival of *I. ricinus* in nature (Perret 2002, Perret et al. 2000, 2004; Burri et al. 2007).

In the context of climate change and with observa-
tions of increasing values and longer lasting periods of high saturation deficits, as for example in the Neuchâtel region (Perret et al. 2000, Morán-Cadenas et al. 2007b), it seemed necessary to study whether infec-
tion by *B. burgdorferi* s.l. may influence *I. ricinus* sur-
vival under thermohygrometric stress conditions.

**Materials and Methods**

**Sampling of Questing Ticks.** The sampling site was a mixed forest (deciduous dominant) situated at 600 m above sea level (47° 00’N, 6° 57’E) on the south-facing slope of Chaumont Mountain (Neuchâtel, Switzerland). Host-seeking ticks were sampled by dragging a 1-m² terry flag over the low vegetation. The flag was examined for ticks every 10 m. Questing nymphs and adults were collected on two different days in May 2009. They were held over water (98% RH) at 4°C for rehydration for 4–6 wk (depending on testing day) as described in Crooks and Randolph (2001) in an iCycler Optical Module (Bio-Rad Laboratories, Reinach, Switzerland) by using strip optical

sealed together by their screw caps with silicone. Screw cap centers had been removed previously and replaced by polyamide mesh (500-μm grid, Sefar-Ni
tex, Sefar AG, Haiden, Switzerland). Arenas stood vertically, with the top culture tube containing ticks and the bottom tube filled two thirds with saturated salt solutions (K₂SO₄, LiCl, MgCl₂, or NaBr), producing known relative humidities at a given temperature based on Winston and Bates (1960). They were ad-
justed after 48-h tests conducted under experimental conditions.

Tick survival was studied under five thermohygro-
metric conditions: 25°C, 89% RH; 12.5°C, 61% RH; 12.5°C, 13% RH; 25°C, 51.5% RH; and 25°C, 32% RH, corresponding to saturation deficits of 2.57, 4.19, 9.35, 11.33, and 15.89 mmHg (1 mmHg = 133.3 Pa), respec-
tively, as calculated by Randolph and Storey (1999). Survival tests were conducted in the dark. Survival of ticks was recorded after 48 h. This duration was de-
termined so that global survival would tend to be 50% based on Perret (2002). All ticks, dead or alive, were then stored at −80°C until analysis for *Borrelia* infec-
tion by real-time polymerase chain reaction (PCR) and reverse line blotting (RLB).

**Borrelia Infection in Ticks.** Before DNA isolation, ticks were soaked in 70% ethanol and air-dried. Ex-
traction of DNA from ticks was achieved using am-
monium hydroxide as described previously (Guy and Stanek 1991, Rijpkema et al. 1996). Negative controls were included during DNA isolation, which consisted of reagents without template DNA.

A real-time PCR amplifying a fragment of the flagel-
lin gene (Schwaiger et al. 2001) was used to detect and quantify *Borrelia* DNA in all field-collected ticks that were subjected to the survival tests. The strain *B. afzelii* NE1817 was used as quantification standard. Spirochete concentration in culture was evaluated by real-time polymerase chain reaction (PCR) and reverse line blotting (RLB).

The 50-μl real-time PCR mixture (Schwaiger et al. 2001) consisted of 5 μl of 10× MgCl₂ buffer, 2 μl of 25 mM MgCl₂, 1 μl of 10 mM dNTPs, 1 μl of 20 μM FlaFL1 forward primer, 1 μl of 20 μM FlaR1 reverse primer, 1 μl of 10 μM FlaProbe1 probe, 0.25 μl of HotStar Taq Polymerase (QIAGEN, Basel, Switzerland), 28.75 μl of water, and 10 μl of the extracted DNA. In each run, one extraction negative control (10 μl; see above), one PCR negative control (10 μl of water instead of 10 μl of the extracted DNA), and three series of the six standards were included.

After an incubation step at 95°C for 10 min, the samples were submitted to 45 repeated amplification cycles (95°C for 15 s, 60°C for 1 min) (Schwaiger et al. 2001) in an iCycler Optical Module (Bio-Rad Labor-
atories, Reinach, Switzerland) by using strip optical
tubes and caps Type F (Life Systems Design, Mersen-

sward, Switzerland).

PCR and RLB were used to identify the Borrelia

species infecting the field-collected ticks. The vari-

able spacer region between two repeated copies of the

23S and 5S ribosomal genes was amplified with primers

23S-Bor and B-5S-Bor (Alekseev et al. 2001). PCR amplifications were run in a Tgradient

Thermocycler 96 (Whatman Biometra, Göttingen,

Germany) by using a touchdown PCR program

(Burri et al. 2007). Positive and negative controls

were included in each PCR. In positive controls,

isolates of B. afzelii (NE632), B. burgdorferi s.s.

(B31), and B. valaisiana (VS116) replaced DNA

samples, whereas water was substituted in negative

controls.

For Borrelia identification by RLB, PCR products

were hybridized to 15 oligonucleotide probes (Ri-

jpkema et al. 1995, Poupon et al. 2006, Gern et al.

2010) blotted in lines on an activated Biodyne C

membrane (Pall Europe Ltd., Portsmouth, United

Kingdom) using a Miniblotter 45 (Immunecon, Cam-

bridge, MA). Hybridization was visualized by incu-
bating the membrane with enhanced chemilumi-

nescence detection liquid (Amersham Biosciences

Europe, Basel, Switzerland) and by exposing the

membrane to X-ray film (Hyperfilm, GE Healthcare,

Little Chalfont, Buckinghamshire, United King-

dom).

Statistical Analysis. All statistics were calculated

with SPSS Statistics 17.0 for Macintosh (SPSS Inc,

Chicago, IL). The relationships between fat content

Statistical Analysis. All statistics were calculated

with SPSS Statistics 17.0 for Macintosh (SPSS Inc,

Chicago, IL). The relationships between fat content

in field-collected nymphs and laboratory-reared

nymphs between infection loads in field-collected

nymphs, males and females, and between Borrelia

genospecies and infection load were evaluated with

the Mann–Whitney test. The \( \chi^2 \) test on contingency

table was used for assessing the influence of life

stages on survival, infection, distribution of Borrelia
genospecies, and distribution of infection load cat-
egories. Influence of the infection, infection load

category, and Borrelia genospecies on survival was

assessed by the \( \chi^2 \) test on contingency table. Influ-

ence of the thermohygrometric factors and infec-
tion load on survival was estimated by binary logistic

regressions.

Results

Fat Content Analysis. Field-collected nymphs con-
tained less fat (8.4%) than field-collected males (16.2%;

Mann–Whitney test, \( P = 0 \)) or females (13.3%; Mann–

Whitney test, \( P = 0.004 \)). In contrast, field-collected

males and females did not differ in lipid content. Labo-

ratory-reared nymphs (control) (14.5%) contained

more fat than field-collected nymphs (8.4%) (Mann–

Whitney test, \( P = 0 \)).

Survival Tests. Globally, there were differences in

survival rates among tick life stages under all five

tested conditions. Laboratory-reared nymphs were

weakly affected by challenging thermohygrometric

conditions showing a survival rate of 95.4% (477/500).

Among field-collected ticks, females displayed the

highest survival rate (77.6%; 388/500), followed by

males (51.6%; 258/500) and nymphs (43.2%; 216/500).

Temperature and relative humidity had a significant

impact on field-collected ticks (binary logistic regres-
sion, temperature: nymph, \( P = 0; \) male, \( P = 0; \) female,

\( P = 0 \) and binary logistic regression, relative humidity:

nymph, \( P = 0; \) male, \( P = 0; \) female, \( P = 0 \)). In contrast,

temperature had no significant influence and relative

humidity a light effect on laboratory-reared nymphs

(binary logistic regression, \( P = 0.119 \) and \( P = 0.027 \),

respectively). More ticks survived when RH increased

and temperature decreased.

SD strongly affected field-collected and laboratory-

reared ticks (binary logistic regression, control, \( P =

0.007; \) nymph, \( P = 0; \) male, \( P = 0; \) female, \( P = 0 \) and

binary logistic regression, relative humidity: \( P = 0 \); male,

\( P = 0; \) female, \( P = 0 \)). In contrast, temperature had no significant influence and relative

humidity a light effect on laboratory-reared nymphs

(binary logistic regression, \( P = 0.119 \) and \( P = 0.027 \),

respectively). More ticks survived when RH increased

and temperature decreased.

Borrelia Infection in Ticks. Among the 1,500 field-
collected ticks that were tested for B. burgdorferi s.l.

by real-time PCR, 34.8% (n = 522) revealed to be

infected: 8.4% (n = 126) were nymphs, 13.2% (n =

198) males, and 13.2% (n = 198) females. Male (39.6%;

198/500) and female ticks (39.6%; 198/500) were more

frequently infected than nymphs (25.5%; 126/500) \( (\chi^2 \)

test, \( P = 0.001 \)). Globally, infection load in these ticks

ranged from 1 to 1.2 million spirochetes per tick. Mean

spirochete number was highest in females (52,400 spi-

Fig. 1. I. ricinus survival rate after 48 h spent under thermohygrometric conditions corresponding to values of saturation
deficit ranging from 2.57 to 15.89 mmHg.
rochetes per tick) and nymphs (18,640 spirochetes per tick). However, the differences were not significant (Mann–Whitney test: nymph-male, \( P = 0.632 \); nymph-female, \( P = 0.823 \); male-female, \( P = 0.560 \)).

To compare the infection loads between adults and nymphs, five infection load categories were arbitrarily chosen: very low (<150 spirochetes per tick), low (151–2,100 spirochetes per tick), medium (2,101–16,000 spirochetes per tick), high (16,001–160,000 spirochetes per tick), and very high (>160,000 spirochetes per tick). Infections in adults fell more often into the high and very high infection load categories (male: 26.8%, 53/198 and female: 19.7%, 39/198) whereas this difference was less marked in males (male: 63,600 and 50,400 spirochetes per tick; female: 86,400 and 78,000 spirochetes per tick, respectively) (Mann–Whitney test: male, \( P = 0.368 \); female, \( P = 0.176 \)).

**Fig. 2.** Mean spirochete load (spirochetes per tick) in nymphal, male and female *I. ricinus* infected by *B. afzelii*, *B. garinii*, and *B. valaisiana*.

Identification of *Borrelia* Species in Ticks. Identification of *Borrelia* genospecies by RLB was possible in 519/522 ticks. Globally, 54% (433/519) of these ticks were infected by one *Borrelia* species, 15% (80/519) by two species and 1% (6/519) by three species (Table 1). Mixed infections were more frequently observed in adults (male: 19.7%, 39/198; female: 16.7%, 33/198) than in nymphs (11.1%, 14/126).

Five *Borrelia* species—*B. afzelii*, *B. burgdorferi* s.s., *B. garinii*, *B. myamotoi*, and *B. valaisiana*—were identified by RLB (Table 1). Taking into account single and mixed infections, *B. afzelii* was the most frequent genospecies (\( n = 207; 39.7\% \)), followed by *B. garinii* (\( n = 198; 37.9\% \)), *B. valaisiana* (\( n = 124; 23.8\% \)), whereas *B. burgdorferi* s.s. was less frequent (\( n = 63; 12.1\% \)). The genospecies that was the least often detected was *B. myamotoi* (\( n = 19; 3.6\% \)), *B. bissettii*, *B. lusitaniae*, and *B. spielmanii*, were not observed.

There was no difference in the distribution of *B. afzelii*, *B. garinii*, and *B. valaisiana* between males and females (\( \chi^2 \) test: *B. garinii*, \( P = 0.416 \); *B. afzelii*, \( P = 0.136 \); *B. valaisiana*, \( P = 0.819 \)). However, important dissimilarities between nymphs and adults were observed in the frequency of some *Borrelia* genospecies. In fact, *B. garinii* and *B. valaisiana* were more frequent in adults than in nymphs (\( \chi^2 \) test: nymph-male, \( P = 0; \) nymph-female, \( P = 0.001 \); nymph-male, \( P = 0.036 \); nymph-female, \( P = 0.022 \), respectively), whereas the contrary was observed for *B. afzelii* (\( \chi^2 \) test: nymph-male, \( P = 0; \) nymph-female, \( P = 0 \)).

Differences in the infection load were found between tick stages according to *Borrelia* species (Fig. 2). In nymphs, infections by *B. garinii* consisted of more spirochetes (78,000 spirochetes per tick) than infections by all other *Borrelia* species (7,680 spirochetes per tick) (Mann–Whitney test, \( P = 0.001 \)), whereas this difference was less marked in males (74,400 and 42,800 spirochetes per tick, respectively; Mann–Whitney test, \( P = 0.028 \)) and in females (60,400 and 52,400 spirochetes per tick, respectively; Mann–Whitney test, \( P = 0.059 \)). In adults, infections by *B. valaisiana* showed less spirochetes (male: 24,520 spirochetes per tick; female: 13,560 spirochetes per tick) than infections by all other *Borrelia* species (male: 62,900 spirochetes per tick; female: 66,400 spirochetes per tick) (Mann–Whitney test: male, \( P = 0.007 \); female, \( P = 0.005 \)). In nymphs, infections by *B. valaisiana* also displayed less spirochetes than all other *Borrelia* species, but the difference was not significant (8,520 and 20,880 spirochetes per tick, respectively) (Mann–Whitney test, \( P = 0.864 \)). Finally, it seemed that nymphs infected by *B. afzelii* (6,880 spirochetes per tick) bore less spirochetes than nymphs infected by other genospecies (41,600 spirochetes per tick) (Mann–Whitney test, \( P = 0.025 \)). Interestingly, the reverse trend was observed in adults, although the difference was not significant (male: 63,600 and 50,400 spirochetes per tick, respectively; female: 86,400 and 44,400 spirochetes per tick, respectively) (Mann–Whitney test: male, \( P = 0.368 \); female, \( P = 0.176 \)).
Effect of *Borrelia* Infection on Tick Survival. Infection load had an effect on adult survival (binary logistic regression, \( P = 0.031 \)) but had no effect on survival of nymphs (binary logistic regression, \( P = 0.553 \)). In adults, survival rate increased as infection load decreased, i.e., a higher infection load negatively influenced adult survival. Specifically, it seemed that infections consisting of \( >160,000 \) spirochetes per tick had a negative impact on adult survival (Fig. 3). In nymphs, however, high spirochete numbers did not negatively influence survival (data not shown).

Based on the results of the survival tests, we considered that thermohygrometric conditions were challenging for ticks when the survival of ticks was below 70%. Because males and females survived well and were affected by thermohygrometric conditions similarly, both categories were merged together to evaluate the SD values corresponding to a survival rate \( \geq 70\% \). These SD values were 4.19, 9.35, 11.33, and 15.89 mmHg in nymphs and 11.33 and 15.89 mmHg in adults. Under these thermohygrometric conditions, infection revealed to have a positive effect on survival of nymphs and adults: 42/98 infected nymphs (42.9\%) and 62/123 infected adults (50.4\%) survived, whereas only 86/302 uninfected nymphs (28.5\%) and 95/251 uninfected adults (37.9\%) survived (\( \chi^2 \) test: nymph, \( P = 0.008 \); adult, \( P = 0.021 \)).

The number of genospecies in the tick had no impact on tick survival (\( \chi^2 \) test, \( P = 0.589 \)). However, differences were observed between *Borrelia* genospecies. Hence, nymphs infected by *B. afzelii* survived better (44.1\%; 26/59) than nymphs that were not infected or infected by other *Borrelia* genospecies (29.9\%; 102/341) (\( \chi^2 \) test, \( P = 0.031 \)). The same trend was observed in adults where a higher survival rate (53.5\%; 23/43) was observed in adults infected by *B. afzelii* than in adults that were not infected or infected by another genospecies (39.5\%; 141/357) (\( \chi^2 \) test, \( P = 0.057 \)).

**Discussion**

**Fat Content Analysis.** In this study, we determined whether *B. burgdorferi* s.l. influenced *I. ricinus* survival under thermohygrometric stress. Fat content in *I. ricinus* was measured to take into account variable energy resources when assessing *I. ricinus* survival. It was observed that fat content in field-collected females was slightly higher than that in field-collected males and considerably higher than that in field-collected nymphs. These results are in line with what is expected because fat content is a source of energy derived from each bloodmeal (Uspensky 1995). Larvae, which ingest less blood than further developmental stages (Ogden et al. 1998), contain less fat than adults as they molt into nymphs. Likewise, nymphal males that take relatively less blood than nymphal females (Graf 1978, Mbow et al. 1994) molt into adult males with smaller energy resources than adult females.

**Survival Tests.** Globally, differences in survival were observed among *I. ricinus* life stages: females survived better (77.6\%) than males (51.6\%), which in turn survived better than nymphs (43.2\%). Lower fat content in nymphs seemed to contribute to lower survival rate. Moreover, adults have a higher water storage capacity due to their size, and their lower surface-to-volume ratio probably allowed them to reduce water loss under dry conditions. Nevertheless the most striking difference in survival lay between laboratory-reared and field-collected nymphs. Although both belonged to the same life stage, the laboratory-reared nymphs survived extremely well (global survival rate, 95.4\%) under any thermohygrometric condition, whereas the field-collected nymphs did not (global survival rate, 43.2\%). This might be explained by the higher fat content, lack of any kind of stress of laboratory-reared nymphs, or a combination. Hence, they had full and ready-to-use stored energy resources when tests began.
Ixodes ticks are exceptionally sensitive to temperature and humidity compared with other ticks (Knüll and Rudolph 1982, Sonenshine 1991). More precisely, it has been observed that I. ricinus most important climatic feature for survival is a high degree of humidity and that increasing temperature limits survival (MacLeod 1935). Saturation deficit, defined as the drying power of the air (Randolph and Storey 1999), also has revealed to influence I. ricinus questing activity (Randolph and Storey 1999; Perret et al. 2000, 2003, 2004) and survival in nature (Perret et al. 2000, 2004; Perret 2002; Burri et al. 2007). Identical observations were made in the current study. Increasing relative humidity influenced positively I. ricinus survival, whereas increasing temperature affected it negatively. As a combination of the last two factors, SD had a stronger impact on I. ricinus than temperature and relative humidity alone. Hence, survival rate was inversely proportional to SD, i.e., more ticks survived as SD decreased.

The latter was true for all field-collected ticks, although it was more marked in nymphs. This matched fat content results: nymphs that had lower fat content than adults survived less well. Thus, it seems to indicate that available energy resources determine life span, which was described in Randolph and Storey (1999), and that more challenging thermohygrometric conditions increase fat usage. This also applies to laboratory-reared nymphs, although results are not as clear-cut as those of field-collected ticks. It may be due to a stress-free state (fully hydrated, high fat) of colony ticks, leading to a very low death rate (4.6%; 23/500) in the survival tests and less straightforward interpretations. However, these results clearly display how different laboratory-reared and field-collected ticks may be.

**Borrelia Infection in Ticks.** Overall prevalence of infection by *Borrelia* (34.8%) was similar to that of another study conducted in the same area (32.7%) (Casati et al. 2004). Infection prevalence in adults was higher (39.6%) than in nymphs (25.5%), as often described in Europe (Rauter and Hartung 2005) and Switzerland (Casati et al. 2004, Jouda et al. 2004). Similarly, adult infections consisted more frequently of >160,000 spirochetes than those of nymphs. These differences in infection prevalence and infection load among stages are probably due to the number and size of bloodmeals taken by ticks in their earlier developmental stages (Ogden et al. 1998).

Genospecies prevalence was in line with what had been observed in the same area: B. afzelii (33.8%), B. burgdorferi s.s. (10.3%), B. garinii (32.1%), B. miyamotoi (3.1%), and B. valaisiana (20.2%) (Casati et al. 2004, Jouda et al. 2004, Morán Cadenas et al. 2007b, Gern et al. 2010). The Borrelia genospecies were similarly distributed among males and females. However, B. afzelii prevailed in nymphs compared with adults, and B. garinii and B. valaisiana were more frequent in adults compared with nymphs. Different favored hosts for bloodmeal and specific host–parasite association may explain this discrepancy (Humair et al. 1995, 1998, 1999; Humair and Gern 1998; Kurtenbach et al. 1998; Morán Cadenas et al. 2007a).

High loads of spirochetes were usually observed in *B. garinii*-infected nymphs and adults, and low loads were observed in *B. valaisiana*-infected mature and immature ticks. B. *afzelii* was observed in low numbers in nymphs, whereas higher numbers of spirochetes were observed in adults. It has been demonstrated that transmission from *I. ricinus* to host differs among *Borrelia* genospecies (Crippa et al. 2002). More precisely, *B. afzelii* is transmitted to host earlier and more efficiently than *B. burgdorferi* s.s. The latter might be true in the opposite direction, i.e., from host to tick. Nymphs that feed for a longer time than larvae may have ingested more *B. afzelii* spirochetes resulting in adults harboring higher borreliae numbers than nymphs. Thus, early-transmitted spirochetes such as *B. afzelii* (Crippa et al. 2002) and probably also *B. garinii* according to the present results may be found in higher numbers in ticks than late-transmitted ones such as *B. burgdorferi* s.s. (Crippa et al. 2002) and supposedly *B. valaisiana*.

Infection load in questing *I. ricinus* in Europe has been investigated by Rauter et al. (2002), who conducted a real-time PCR targeting the ospA gene (compared with a fragment of the flagellin gene here). They reported a median of 4,000 spirochetes per tick, which is higher than the one observed in the current study (2,760 per nymph; 1,496 per male; 2,075 per female). However, Rauter et al. (2002) did not discriminate between life stages or between *Borrelia* genospecies (both factors have been shown to significantly influence infection load).

**Effect of Borrelia Infection on Tick Survival.** In view of the present results, the hypothesis that infection by *B. burgdorferi* s.l. enhances *I. ricinus* survival under thermohygrometric stress conditions is confirmed. However, the phenomenon does not apply in every situation and acts subtly. Its impact varies between life stages, as well as according to infection load. Hence, nymphal survival revealed to be highly positively influenced by infection by *Borrelia*, whatever the infection load. In contrast, adults seemed to be positively influenced by spirochete colonization up to a threshold of infection load (estimated at 160,000 spirochetes per tick), where an increasing number of borreliae became harmful and the positive effect was reversed to a negative effect. That this deleterious effect of spirochete “overdose” was observed in adults but not in nymphs is probably related to the extremely rare proportion of nymphs bearing >160,000 spirochetes per tick (1.6%; 2/126) compared with adults (8.6%; 34/396). Thus, a potentially negative effect of infection load could not be detected in nymphs due to poor occurrence of very high infection load. Very high *Borrelia* numbers might trigger *I. ricinus* immune response (Coleman et al. 1997, Johns et al. 2001, Sonenshine and Hynes 2008) requiring too much energy resources. That would, in turn, reduce energy allowance to other stress sources such as challenging thermohygrometric conditions thereby impairing vector resistance to heat and/or desiccation.
Although the number of different genospecies infecting the tick did not impact on tick survival, one particular genospecies, *B. afzelii*, revealed to be positively associated with *I. ricinus* survival, especially in nymphs. Therefore, ticks infected by *B. afzelii* had an advantage over uninfected ticks or those infected by other *Borrelia* genospecies when stressed by unfavorable thermohygrometric conditions. Interestingly, it has been observed during the past decade that infection rate by *B. afzelii* in *I. ricinus* has increased in the Neuchâtel region (L.G., unpublished data) where hot and dry climatic conditions have been shown to have a negative impact on questing tick densities (Perret et al. 2000, 2004; Morán Cadenas et al. 2007b).

Various hypotheses can be put forward to explain the higher survival rate of ticks infected by *Borrelia* observed in the current study. Although spirochetes in questing ticks are usually limited to the tick midgut, they may be disseminated in other tissues and organs producing a systemic infection in up to 11% of *I. ricinus*-infected nymphs (Burgdorfer et al. 1989, Lebet and Gern 1994). Hence, we can surmise that spirochetes in the midgut and those that are systemically distributed in the tick might be able to modify the physiology, metabolism, or both, of organs, such as those involved in bloodmeal digestion or water sorption/loss, resulting in optimized blood digestion, increasing energy resources or optimized water sorption/retention enhancing water storage, respectively.

However, it is known that infection by *Borrelia* can change gene expression in ticks as observed in *I. scapularis*. It was shown that the expression of one gene was selectively increased in salivary glands of *I. scapularis*. (Schouls et al. 2001). The molecular mechanisms at the tick–pathogen interface that are responsible for the higher survival rate of *I. ricinus* ticks infected by *Borrelia* spp. remain to be investigated and additional studies are expected in this subject. According to our results, infection by *B. burgdorferi* s.l. provides a survival advantage to *I. ricinus* ticks under challenging conditions of temperature and humidity. In fine, both organisms take advantages from each other, hence such a mutualism may have accompanied the entire evolution of *Borrelia* together with their tick vectors.

### Acknowledgments

We thank Luca Gigandet, and Kangaji Kasongo for help in collecting ticks; Olivier Rais, Francisca Morán Cadenas, Caroline Burri, and Elena Lomanno for precious technical help and advice; and Jason Grant for reviewing the English of the manuscript. Results obtained here are part of a project financed by the Swiss National Science Foundation (FN 320030_113936 and FN 310030_127064) to L.G. Some of the results are part of the Ph.D. dissertation of C.H.
