Improving Compliance With Hand Hygiene in Hospitals

Didier Pittet, MD, MS

ABSTRACT

Hand hygiene prevents cross-infection in hospitals, but compliance with recommended instructions often is poor among healthcare workers. Although some previous interventions to improve compliance have been successful, none has achieved lasting improvement. This article reviews reported barriers to appropriate hand hygiene and factors associated with poor compliance.

Easy access to hand hygiene in a timely fashion and the availability of skin-care lotion both appear to be necessary pre-requisites for appropriate hand-hygiene behavior. In particular, in high-demand situations, hand rub with an alcohol-based solution appears to be the only alternative that allows a decent compliance.

The hand-hygiene compliance level does not rely on individual factors alone, and the same can be said for its promotion. Because of the complexity of the process of change, it is not surprising that solo interventions often fail, and multimodal, multidisciplinary strategies are necessary. A framework that includes parameters to be considered for hand-hygiene promotion is proposed, based on epidemiologically driven evidence and review of the current knowledge. Strategies for promotion in hospitals should include reasons for noncompliance with recommendations at individual, group, and institutional levels. Potential tools for change should address each of these elements and consider their interactivity (Infect Control Hosp Epidemiol 2000;21:381-386).

DEFINITIONS

Three groups of microorganisms may be distinguished on the skin: organisms that reside on the skin (resident flora), those that happen to be there as contaminants (transient flora), and pathogens responsible for infections, such as paronychia or panaritium digiti (infectious flora). Unless introduced into body tissue by trauma or in conjunction together with foreign bodies, such as intravenous catheters, the pathogenic potential of the resident flora is usually regarded as low. In contrast to natural resident flora, transient flora are responsible for most nosocomially acquired infections resulting from cross-transmission, but are easily removed by hand cleansing.

Hand hygiene (not including surgical hand scrub) defines several actions designed to decrease hand colonization with transient flora and can be achieved either through hand washing or hand disinfection. Hand washing refers to the action of washing hands with an unmedicated detergent and water, or water alone, to remove dirt and loose transient flora to prevent cross-transmission. Hygienic hand wash refers to the same procedure when an
antiseptic agent is added to the detergent. Hand disinfection refers to any action where an antiseptic solution is used to clean hands (either medicated soap or alcohol). Some experts may refer to the action of de-germing with detergent-based antiseptics or alcohol. Hygienic hand rub consists in rubbing hands with a small quantity (2-3 mL) of a highly effective and fast-acting antiseptic agent.

Because alcohols have excellent antimicrobial activity and the most rapid action of all antiseptics, they are the preferred agents for hygienic hand rub (also called waterless hand disinfection). Of particular importance is that alcohols dry very rapidly, allowing for fast hand disinfection without the need to return to the sink constantly, to wash hands with water and soap, to dry them, and to come back to the patient bedside to resume care. Because alcohol alone does not have any lasting effect, another compound with antiseptic activity is sometimes added to the hand-disinfection solution to obtain a prolonged effect. The main antiseptics recently were reviewed extensively by Rotter.22

### COMPLIANCE WITH HAND HYGIENE

Compliance with hand-hygiene recommendations usually is below 50% (Table 1). Although opportunities for hand hygiene were not recorded in a standardized manner in these studies, it is still fair to say that compliance was almost universally low. As shown, it varied according to the hospital ward where the observation was conducted. In most surveys, compliance was observed more frequently in nurses than physicians.

### BARRIERS TO APPROPRIATE HAND HYGIENE

Perceived barriers to appropriate hand hygiene have been reported by HCWs.20,23-28 These include reasons as different as the following: hand hygiene agents cause skin irritation and dryness; patient needs take priority over hand hygiene; sinks are inconveniently located or not available; glove use dispenses with the need for additional hand hygiene; HCW has inadequate knowledge of guidelines or protocols for hand hygiene; there is lack of role models (superiors or peers); there is lack of recognition of the risk of cross-transmission of microbial pathogens; or simply forgetfulness.

Some of these perceived barriers have been assessed or even quantified in observational studies.20,23-28 Table 2 lists 20 reasons for poor compliance. Some are discussed below.

Skin irritation by hand-hygiene agents constitutes an important barrier to appropriate compliance. The superficial skin layers contain water to keep the skin soft and pliable, and lipids to prevent dehydration of the corneocytes. Hand cleansing can increase skin pH, reduce lipid content, increase transepidermal water loss, and even increase microbial shedding. Soaps and detergents are damaging substances when applied to skin on a regular

Abbreviations: HCW, health care worker; ICU, intensive care unit.

🔹 X refers to reasons for poor compliance with hand hygiene that have been frequently self-reported or have been observed in observational or analytical studies.

(X) refers to reasons for poor compliance with hand hygiene that have been self-reported on occasion in the “Discussion” section of a paper, but have not been confirmed in observational or analytical studies.

* As assessed by a high number of opportunities for hand hygiene per hour of patient care.
basis. Importantly, however, HCWs need to be informed better about the possible effects of hand-hygiene agents. Lack of knowledge and education on this topic is a key barrier to motivation. In particular, it is extremely important to recall that alcohol-based formulations for hand disinfection (whether isopropyl, ethyl, or n-propanol, in 60%-90% vol/vol) are less irritating to skin than any antiseptic or nonantiseptic detergents; alcohols, with the addition of appropriate emollients, are at least as tolerable and as efficacious as detergents; emollients may even be protective against cross-infection by keeping the resident skin flora intact; and hand lotions help to protect skin and may reduce microbial shedding. These issues recently were reviewed in detail by Elaine Larson.

The need for ready access to hand-hygiene supplies, whether sink, soap, medicated detergent, or waterless alcohol-based hand-rub solution, is self-evident. Asking busy HCWs to walk away from the patient bed to reach a wash basin or to get a hand antisepsis solution invites noncompliance with hand-hygiene recommendations. Engineering controls could facilitate compliance, but careful monitoring of hand-hygiene behavior should be conducted to exclude possible negative effects of newly introduced devices.31

Wearing of gloves might represent a barrier for compliance with hand hygiene.32 Noncompliance has been identified among glove users in at least two studies.19,30 It is important to recognize that hand hygiene is required whether or not gloves are used or changed. Failure to remove gloves after patient contact or between dirty and clean body-site care on the same patient has to be regarded as noncompliance with hand-hygiene recommendations. Engineering controls could facilitate compliance, but careful monitoring of hand-hygiene behavior should be conducted to exclude possible negative effects of newly introduced devices.31

Among them, being a physician or a nursing assistant rather than a nurse was commonly associated with reduced compliance.

In the largest survey conducted so far,20 we also identified predictors of noncompliance with hand hygiene during routine patient care using a hospitalwide survey. Predictor variables included professional category, hospital ward, time of day or week, and type and intensity of patient care (defined as the number of opportunities for hand hygiene per hour of patient care). In 2,834 observed opportunities for hand hygiene, average compliance was 48%. In multivariate analysis, noncompliance was lowest among nurses, compared with other HCWs, and on weekends (odds ratio [OR], 0.6; 95% confidence interval [CI 95], 0.4-0.8); it was higher in intensive care units (compared with internal medicine: OR, 2.0; CI 95, 1.3-3.1); and when intensity of patient care was high (compared with 0-20 opportunities: 21-40 opportunities: OR, 1.3; CI 95, 1.0-1.7; 41-60 opportunities: OR, 2.1; CI 95, 1.5-2.9; >60 opportunities: OR, 2.1; CI 95, 1.3-3.5). This study confirmed modest levels of compliance with hand hygiene in a teaching institution and showed that compliance varied by hospital ward and by type of HCW, thus suggesting that targeted educational programs might be useful. Most importantly, high demand for hand hygiene (ie, overwork) was associated with low compliance. The results of this study also suggested that full compliance with current guidelines may be unrealistic20,29,32 and that facilitated access to hand hygiene could help improve compliance.

**IMPROVING COMPLIANCE WITH HAND HYGIENE**

Educational programs, distribution of information leaflets, workshops and lectures, automated dispensers, and performance feedback on hand-hygiene compliance rates have been associated with, at best, transient improvement in hand-hygiene rates.2,16,18,24,36,37

No single intervention has consistently been shown to sustain improved compliance with respect to HCWs’ infection control practices.27 The most effective strategy documented so far has been routine observation and feedback.19,24,37 In 1998, Kretzer and Larson28 revisited the major behavioral theories and their applications with regard to the health professions in an attempt to understand better how one might plan more successful interventions. They proposed a hypothetical framework to enhance hand-hygiene practices and stressed the importance of considering the complexity of individual and institutional factors when designing behavioral interventions.

Behavioral theories and secondary intervention have primarily targeted individuals. We agree with Kretzer and Larson26 that this is insufficient to effect sustained change28,29,32 and that interventions aimed at improving compliance with hand hygiene must consider the various levels of behavior interaction.38,20,40 Thus, the interdependence of individual factors, environmental constraints, and the institutional climate all need to be taken into account in the strategic
planning and development of hand-hygiene promotion campaigns.28,29,30 Parameters associated with noncompliance with hand-hygiene recommendations are related not only to the individual HCW but also to the group he or she is working in and, by extension, to the institution to which the latter belongs (Table 3). Interventions to promote hand hygiene in hospitals should consider variables at all of these levels.

The dynamics of behavioral change are complex. It involves a combination of education, motivation, and system change. The factors necessary for a change include the dissatisfaction with the current situation, the perception of alternatives, and the recognition, both at the individual and institutional level, of one's ability and potential to change. While the latter implies education and motivation, the former two necessitate primarily a system change.

Reported reasons for noncompliance include the lack of hand-hygiene promotion, active participation at the individual and institutional level, the frequent lack of a role model by senior staff, the lack of institutional priority for hand hygiene, the lack of administrative sanctions for non-compliers or the rewarding of compliers, and the lack of an institutional safety climate. The latter would involve top-management commitment, visible safety programs, a low level of work stress, a tolerant and supportive attitude toward reported problems, and belief in the efficacy of preventive strategies.28,29,30,41

**TOOLS FOR CHANGE**

An improvement in infection control practices requires the following: questioning basic beliefs; continuous assessment of the group’s (or individual’s) stage of behavioral change; intervention(s) with an appropriate process of change; and supporting individual and group creativity.28 Because of the complexity of the process of change, it is not surprising that single interventions often fail. Thus, a multimodal, multidisciplinary strategy is necessary.

Table 4 proposes a framework that includes parameters to be considered for hand-hygiene promotion. Some of these are based on epidemiologically driven evidence, others on the authors’ and other investigators’ experiences and review of the current knowledge. Some of these parameters may be unnecessary in some circumstances, but may help in others. In particular, changing the hand-hygiene agent could be beneficial in institutions or hospital wards with a high work load and a high demand for hand hygiene when waterless hand rub is not available.3,4,20,42 A change in the recommended hand-hygiene agent could however be deleterious if introduced during the winter, at a time of higher skin irritability.

As explained previously, several parameters that potentially could be associated with successful promotion of hand hygiene need, or would require, a system change (Table 4). Once again, hand-hygienic compliance does not rely on individual factors alone, and the same can be said for its promotion. Enhancing individual and institutional capabilities to organize and execute actions to reach the objective, obtaining active participation at both levels, and promoting an institutional safety climate represent major challenges that go well beyond the current perception of the infection control practitioner’s common role. This, however, should not stop this effort. As a French proverb says, “Les petits ruisseaux font les grandes rivières” (great oaks from little acorns grow).

Easy access to hand hygiene in a timely fashion and the availability, free of charge, of skin-care lotion both appear to be necessary prerequisites for appropriate hand-hygiene behavior and are easier to obtain than major system change. In particular, in high-demand situations, such as in most critical-care units, in high-stress working conditions, and at times of overcrowding or understaffing, hand rub with an alcohol-based solution appears to be the only alternative that allows decent compliance.

TABLE 5  
HAND-HYGIENE RESEARCH ISSUES

How can more definitive scientific evidence for the impact of 
 improved compliance with hand hygiene on infection rates be 
generated?

How much hand washing is enough?
What percentage increase in hand hygiene does it take to achieve a 
predictable risk reduction in infection rates?
Should we encourage or discourage the use of gloves?
What are the key determinants of hand-hygience behavior and 
promotion?
Should hand disinfection replace conventional hand washing?
What are the most suitable hand-hygience agents? Should 
hand-hygience solutions include a long-lasting compound?
How can top-management support be obtained?

And last but not least (Table 4), strategies to improve 
compliance with hand-hygience practices should be multi-
modal and multidisciplinary. It is important to note, 
ever, that the proposed framework needs further research 
before implementation.

AGENDA FOR RESEARCH

Many questions remain unanswered, and this review 
may bring more questions than answers to infection control 
practitioners. Table 5 lists some of the key questions for 
infection control practitioners, laboratory research scienti-
ests, and behavioral epidemiologists regarding the prac-
tices of hand hygiene in the healthcare setting today.

The challenge of hand-hygience promotion could be 
summarized in one single question, “How to change 
HCWs’ behavior?” Tools for change are known but need to 
be tested. Some may prove to be irrelevant in the future; 
others have worked in some institutions and need to be 
tested in others. Behavioral epidemiology is a science, and 
research in behavior change is a research; funding agen-
cies must be convinced that good research needs resour-
ces, and peer-review journal editorial boards and fac-
culty chairpersons need to reconsider their views on this 
matter. Our job, as infection control professionals, is to pro-
vide outstanding research and practical solutions to 

improve our understanding and the impact of hand-hygience 
promotion, to the ultimate benefit of the patient.

Proposed Tuberculin PPD-S2 as Reference Standard

Gina Pugliese, RN, MS
Martin S. Favero, PhD

Since 1951, the tuberculin PPD-S1 has been used to standardize commercial PPD reagents and perform special tuberculin surveys. PPD-S1 is now in short supply, and a new standard (PPD-S2) has been manufactured. To determine if PPD-S2 is equivalent and can replace PPD-S1, Villarino and coinvestigators from the CDC; the FDA; Seattle-King County Health Department, University of California, San Diego; University of Arizona, Tucson; Emory University, Atlanta, Georgia; Marion County Health Department, Indianapolis, Indiana; and Denver Public Health Department, Denver, Colorado, conducted a double-blind clinical trial. Between May 14 and October 28, 1997, 69 subjects with a history of culture-proven TB (TB patients) and 1,189 subjects with a very low risk for TB infection were enrolled, received four skin tests (with PPD-S1, PPD-S2, and one each of the commercially available PPDs), and had reactions measured by two trained observers. Among the TB patients, there was statistically indistinguishable immunogenicity (mean reaction size±standard deviation): 15.6±6.6 mm for PPD-S1 and 14.8±5.6 mm for PPD-S2, and had reactions measured by two trained observers. Among the low-risk subjects, the tests had equally high specificities (PPD-S1, 98.7%; PPD-S2, 98.3%), using a 10-mm cutoff. The number of discordant (negative vs positive) interpretations for PPD-S2, assuming that low-risk subjects who had a >10 mm reaction to PPD-S1 were truly infected, was low (0.5%) and indistinguishable from the rate of discordant interpretations of the same test when read by two different observers (0.8%).

The study results indicate that PPD-S2 is qualified to be used as the new US reference standard for PPD tuberculin.
