

Low-temperature solid-oxide fuel cells based on proton-conducting electrolytes

Emiliana Fabbri, Anna Magrasó, and Daniele Pergolesi

The need for reducing the operating temperature of solid-oxide fuel cells (SOFCs) imposed by cost reduction has pushed significant progress in fundamental understanding of the individual components, as well as materials innovation and device engineering. Proton-conducting oxides have emerged as potential alternative electrolyte materials to oxygen-ion conducting oxides for operation at low and intermediate temperatures. This article describes major recent developments in electrolytes, electrodes, and complete fuel cell performance for SOFCs based on proton-conducting electrolytes. Although the performance of such fuel cells is still relatively modest, significant improvements in the power density output have been made during the last couple of years, and this trend is expected to continue.

Introduction

Solid-oxide fuel cells (SOFCs) are electrochemical devices that convert chemical energy from a fuel into electrical energy with high efficiency (see the Introductory article in this issue). The small environmental impact, fuel flexibility, and wide scalability are among the most appealing advantages of this technology, making SOFCs important players for the development of a global sustainable power generation system.¹

The main drawback of this technology is the limited lifetime of the fuel cell stack. This is due to the high operating temperature (above 800°C) required to promote sufficient catalytic activity for the oxygen reduction reaction (ORR) at the cathode and adequate ionic conductivity across the electrolyte. Materials instability (degradation, segregation, inter-diffusion) is the direct consequence of such high operating temperatures, which hinder the full exploitation of SOFC technology. Many efforts are being devoted to overcome this problem by trying to identify a suitable coupling between cathodes and electrolytes, allowing efficient cell operation in the so-called low temperature range (LT, 400–600°C).² A reduction of the SOFC operating temperature down to this range would provide enormous advantages, widening the range of suitable materials while still preserving good catalytic activity, including direct hydrocarbon reforming at the electrodes.

Concerning the electrolyte materials, two approaches can be followed to decrease ohmic losses at reduced temperatures:

Decreasing the electrolyte thickness and/or using alternative materials with higher ionic conductivities in the low and intermediate temperature range.

Current SOFC technology is based on oxygen-ion conducting electrolytes, such as yttria-stabilized zirconia (YSZ) or doped ceria. As an alternative, high-temperature proton conductors (HTPCs) can be used as electrolyte materials in SOFCs (H⁺-SOFCs).³ HTPCs are conductive oxide materials, where protons are the dominant charge carriers when exposed to a humidified and/or H₂-containing gaseous environment. Typical HTPC materials are barium-based perovskite oxides (cerates or zirconates), as well as rare-earth ortho-niobates and tungstates. These materials show activation energies for proton mobility between 0.4 and 0.6 eV, significantly lower than that of oxygen-ion conducting electrolytes. This means that larger conductivities may be achieved at lower temperatures using HTPCs. Moreover, H⁺-SOFCs produce water as the by-product at the cathode side instead of the anode, therefore avoiding the dilution of the fuel and minimizing re-oxidation of the anode.

Proton-conducting electrolyte materials Perovskite oxides

The most studied HTPCs are oxides with the perovskite-type structure (ABO₃), where the A-cation is an alkaline earth element, such as Ba, Sr, and Ca, while the B-cation is

a tetravalent element, usually Ce or Zr. To promote protonic conductivity, the B-site is partially substituted with trivalent elements such as Y, In, or Gd, leading to the formation of oxygen vacancies. Proton conduction occurs mostly through the dissociation of water from the gas phase into a hydroxide ion and a proton; the former fills an oxygen vacancy, while the latter forms a hydrogen bond with lattice oxygen.³ The reaction generates two protonic defects. These protons can be highly mobile and migrate by a hopping mechanism from one oxygen atom to the next (**Figure 1a**).

According to the most accepted model,^{4–6} thermal vibrations of the perovskite BO_6 octahedra lead to chaotic fluctuations in the vicinity of the O atoms involved in the hydrogen bonding. Then, the distance between two adjacent oxygen atoms can briefly become short enough to allow the hydrogen to overcome the potential barrier and hop to the neighboring oxygen (proton transfer). At the same time, thermal vibrations also favor local elongations of the O–H link, which becomes weaker and eventually breaks, leaving the proton free to bond with another oxygen atom (re-orientation and rotational diffusion). These two mechanisms complement each other, resulting in continuous low-energy proton-diffusion pathways.⁵ The energetics of these two mechanisms is consistent with an activation energy of about 0.15 eV or lower. However, in cubic perovskite oxides, the experimental activation energy is $\sim 0.4\text{--}0.6$ eV.⁴ Such a discrepancy has been experimentally rationalized by the effect of proton trapping.⁷ In the case of Y-doped barium zirconate, the incorporated protons are trapped at the dopant sites, adding an additional potential barrier for long-range diffusion.

The most investigated HTPCs are 10–20 at.% Y-doped barium zirconate (BZY) and barium cerate (BCY).³ BZY exhibits good chemical stability in fuel cell operating conditions and

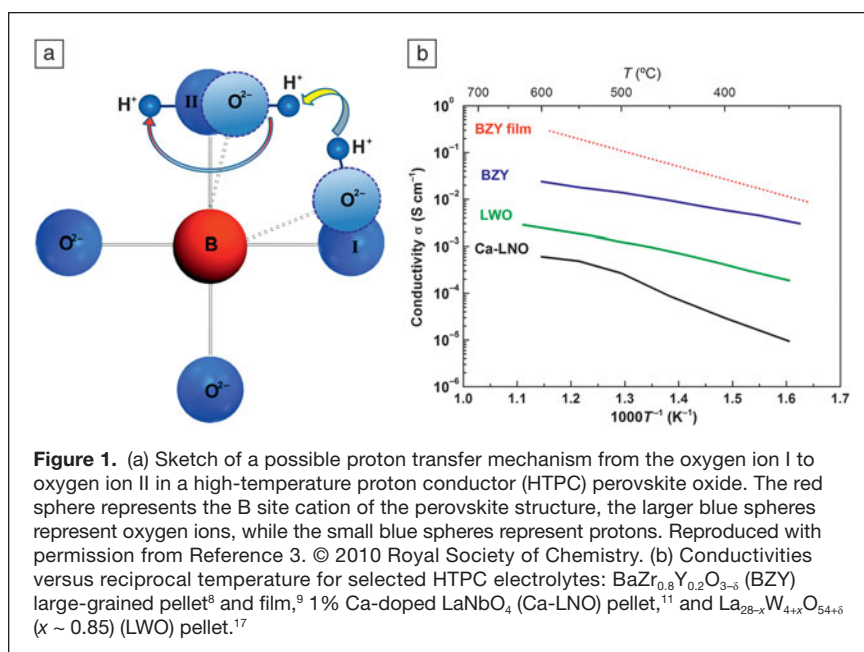

high grain interior (bulk) conductivity, but the grain boundary regions block the proton migration. Moreover, BZY is a highly refractory material, and generally very high temperatures (above 1700°C) are required to sinter dense ceramic pellets. Such high temperatures lead to BaO evaporation, and the Ba loss favors the Y substitution into the A sites of the perovskite structure. As a result, oxygen vacancies are consumed, thereby reducing the number of charge carriers. Lower sintering temperatures, suitable for preserving the required composition, lead to high porosity and/or low average grain size with extended grain boundary regions. As a consequence, the total electrical conductivity of BZY sintered pellets is too low for practical applications. On the other hand, BCY sintered pellets have overall good conducting properties, but the main drawback is the low chemical stability in the operating environment for SOFCs, since BCY reacts with water vapor and CO_2 .³

Many efforts have emerged to either improve the chemical stability of BCY or the sinterability of BZY. The latter strategy turned out to be particularly effective, since an experimental protocol for the synthesis of BZY ceramic pellets without the use of sintering aids and leading to an average grain size in the micrometer range has been recently reported.⁸ The literature also reported the fabrication of highly ordered (grain boundary free) BZY thin films grown by pulsed laser deposition, which allows direct access to the very high bulk conductivity of this material.^{9,10} The proton conductivities in the LT range of BZY (as sintered pellets with micrometer grain size and as an epitaxial thin film) are reported in Figure 1b.

Non-perovskite materials

After the discovery of proton conductivity in perovskites, alternative materials were studied with the aim of finding other compositions that could combine high proton conductivity and chemical stability. Ternary oxides with A-site rare-earth cations (La or other rare-earth elements but avoiding basic alkaline cations, such as Ba or Sr) caught the interest of researchers based on literature reports of considerable proton conductivities in several families of materials, including rare-earth niobates and tungstates.

Acceptor-doped lanthanum ortho-niobate (Ca-doped LaNbO_4) exhibits a phase transition from monoclinic (Fergusonite-type structure) to a tetragonal phase (Scheelite phase) around 500°C and shows proton conductivity on the order of $\sim 5 \times 10^{-4}$ S cm^{-1} at 600°C (see Figure 1b).¹¹ According to first-principle calculations, the rate-determining process for proton migration in LaNbO_4 is the rotation and hopping between two adjacent tetrahedra (inter-tetrahedral proton transfer). Activation enthalpies of proton mobility are about 0.36 and 0.59 eV in the tetragonal and the monoclinic

phases, respectively.¹² This material exhibits dominant proton conductivity under wet conditions below ~850°C and is stable in atmospheres containing CO₂ under fuel cell operation.¹³ This promising discovery initiated research efforts to study this material further and search for the optimal cation composition. However, LaNbO₄ is a so-called line compound (i.e., which does not tolerate large non-stoichiometries), thus implying that the solubility for acceptor doping or tolerance toward segregation of phases is quite limited. Even though various doping strategies have been attempted, the protonic conductivity could not be increased further.¹⁴

Lanthanum tungstate with a fluorite-type structure has been reported to be proton conducting by hydration at low temperatures.^{15,16} Early work reported that this fluorite phase corresponded to a stoichiometry of La₆WO₁₂, but this phase is not stable and must be prepared La-deficient to be single phase.¹⁷ The established composition nowadays is La_{28-x}W_{4+x}O_{54+δ} (LWO), where nearly one tungsten dissolves in lanthanum sites to form a stable solid-state electrolyte.¹⁸ The protonic conductivity of undoped LWO is above 10⁻³ S cm⁻¹ at 600°C.¹⁶ However, as shown in Figure 1b, this value is still lower than that reported for the best Ba-based perovskites.

An advantage of LWO versus LaNbO₄ is that the former does not exhibit any phase transition with temperature or by hydration and remains cubic from room temperature up to 800°C.¹⁹ Additionally, LWO tolerates variations in the La/W ratio without segregation of phases (i.e., it is not a line compound).¹⁷

Electrode materials

In H⁺-SOFCs, water is produced at the cathode side; the cathodic oxygen reduction reaction has much slower kinetics than the hydrogen reduction at the anode side (when H₂ is used as the fuel), and therefore the cathode is generally the source of the largest overpotential associated with the electrode reactions. The oxygen reduction at the cathode comprises several reactions steps, summarized in **Table I**, which can vary depending on the cathode material.²⁰ As shown in **Figure 2**, molecular oxygen adsorption occurs at the cathode surface followed by oxygen dissociation. In the case of a mixed O²⁻/e⁻ conducting cathode (Figure 2a) or a composite cathode made of a mixed O²⁻/e⁻ conductor and a proton conductor (Figure 2c), the adsorbed oxygen can diffuse on the surface of the mixed O²⁻/e⁻ conductor toward the reaction area, where it reacts with two electrons and two protons to form water. For a mixed H⁺/e⁻ conducting cathode (Figure 2b), the oxygen does not need to migrate toward the reaction site because protons and electrons can migrate within the whole cathode material.

Only recently have research efforts been oriented toward the development of specifically designed cathode materials for H⁺-SOFCs.²⁰ While the use of a mixed oxygen-ion/electron (O²⁻/e⁻) conductor results in confinement of the reaction sites to the electrode/electrolyte interface (Figure 2a), a mixed proton/electron (H⁺/e⁻) conductor would allow extending the reaction area to the whole cathode surface, thus facilitating the evaporation of the water by-product (Figure 2b). An alternative way to extend the reaction area is the development of composite cathodes made of a mixed O²⁻/e⁻ conductor and a H⁺-conducting oxide (Figure 2c).²⁰

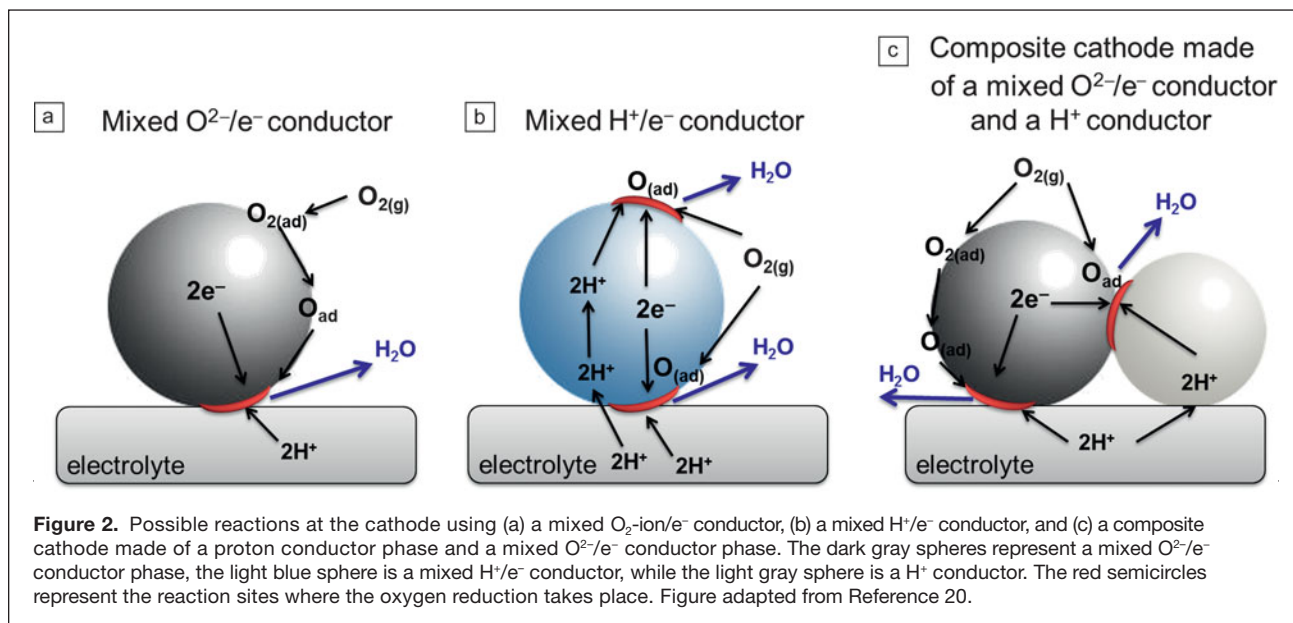

In the case of perovskite-type electrolytes, growing interest has recently been directed toward the development of mixed H⁺/e⁻ conducting oxides. Mixed H⁺/e⁻ conductivity in a wet oxidizing atmosphere can be obtained by doping the B-sites of BaZrO₃ with Y and Pr, due to the mixed 3+ and 4+ valence state of Pr. As an example, the composition BaZr_{0.6}Pr_{0.3}Y_{0.2}O_{3-δ} showed good chemical stability and a mixed H⁺/e⁻ conductivity in humidified air.²¹ Consistent results were also obtained doping BaZrO₃ with Pr and Gd, with an optimized composition of BaZr_{0.6}Pr_{0.3}Gd_{0.1}O_{3-δ}.^{22,23} Following a similar strategy, transition metals such as Co and Fe were introduced into the lattice of BaCeO₃ and BaZrO₃ perovskites.²⁴⁻²⁶ However, the value of the partial electronic conductivity, where reported, of such mixed H⁺/e⁻ conductors is too low for application as a single-phase cathode material. Recently, it has been suggested that typical cathode materials used in SOFCs based on oxygen-ion conducting electrolytes, besides being mixed O²⁻/e⁻ conductors, might also present some level of proton conductivity.^{27,28} In particular, it has been proposed that perovskites with significant oxygen deficiency, such as Ba_{0.5}Sr_{0.5}Co_{0.8}Fe_{0.2}O_{3-δ} and PrBaCo₂O_{5-δ}, might allow the largest degree of proton insertion.²⁸ However, the suggestion of proton conduction in mixed O²⁻/e⁻ conductors is still controversial, and further investigations are required to unambiguously prove the presence of a protonic contribution to the total conductivity.

Encouraging results were also reported on the development of composite cathode materials. For example, a relatively low area specific resistance (ASR) of 0.16 Ω cm² was obtained at 600°C for a composite cathode made of

Table I. Possible elementary cathode reaction steps in a H⁺-solid-oxide fuel cell.

$O_{2(g)} \rightarrow O_{2(ad)}$	Oxygen adsorption
$O_{2(ad)} \rightarrow 2O_{(ad)}$	Oxygen dissociation
$O_{(ad)}^- \rightarrow O_{(ad)RS}^-$	Oxygen surface diffusion toward the reaction site
$2H_{bulk}^+ \rightarrow 2H^+$	Proton migration toward the reaction site
$O_{(ad)}^- + 2e^- \rightarrow O_{(ad)}^{2-}$	Oxygen reduction
$H^+ + O^{2-} \rightarrow OH^-$	Hydroxide formation
$OH^- + H^+ \rightarrow H_2O$	Water formation
$H_2O \rightarrow H_2O_{(g)}$	Water evaporation

The elementary reaction steps described are also illustrated in Figure 2 for different cathode materials.

$La_{0.5}Sr_{0.5}Co_{0.6}Fe_{0.4}O_{3-\delta}$ and $BaZr_{0.5}Pr_{0.3}Y_{0.2}O_{3-\delta}$,²⁹ where the former is a mixed O^{2-}/e^- conductor, and the latter is a mixed H^+/e^- conductor.

The microstructure also plays an important role in achieving low overpotentials. Advanced cathode microstructures were obtained at relatively low processing temperatures, avoiding cation interdiffusion, by infiltration of $LaCoO_3$ into a porous backbone of Ba-Ce-Zr-based oxide.³⁰

Regarding the anodic electrode, most of the H^+ -SOFCs utilize composite anodes fabricated by mixing NiO with the same material used for the electrolyte. Conversely, anodes for the LWO electrolyte cannot be prepared in this “traditional” manner, as it reacts with NiO, and alternative fabrication routes have been reported.³¹ Two general drawbacks are associated with the use of Ni for the fabrication of the anode. First, Ni tends to agglomerate, resulting in deterioration of anode performance with time. Additionally, when hydrocarbons are used as the fuel, coke formation strongly hinders Ni-based anode performance. Moreover, the chemical stability of the H^+ -conducting phase in the anode is obviously a further important issue when carbon-containing compounds are used as a fuel.

Fuel cell performance

As outlined previously, the main issues related with reducing SOFC operating temperature are the increased electrolyte resistivity and electrode polarization. In addition to improving the electrolyte conduction properties and electrode kinetics, modifying the fuel cell design might also assist in overcoming these drawbacks. Making the anode the supporting structure for SOFC fabrication allows the electrolyte to be implemented as a thin layer, thereby minimizing ohmic loss. Several ceramic processing methods have been proposed to fabricate anode-supported H^+ -SOFCs. Most of the tested H^+ -SOFCs on the

laboratory scale are fabricated by a co-pressing and co-firing technique,³² which generally allows a minimum electrolyte thickness (capable of preventing reactant cross-over) of $\sim 15 \mu\text{m}$ to be supported on a porous anode structure, as shown in **Figure 3**.³³

The development of anode-supported H^+ -SOFCs based on doped- $BaZrO_3$ electrolytes is complicated by the poor sinterability of this material. This problem has been addressed following different approaches; by using doping elements able to favor the sinterability (i.e., $BaZr_{0.7}Pr_{0.1}Y_{0.3}O_{3-\delta}$,³⁴ $BaZr_{0.7}Sn_{0.1}Y_{0.3}O_{3-\delta}$,³⁵ $BaZr_{0.8}In_{0.2}O_{3-\delta}$ ^{36,37}), by the addition of sintering aids,^{38–40} or by using anodes able to promote electrolyte sinterability.^{41,42} Several H^+ -SOFCs have also been developed using a solid solution of barium zirconate and barium cerate (e.g., $BaCe_{0.7}Zr_{0.1}Y_{0.2}O_{3-\delta}$) as an electrolyte.³² However, it has been recently shown that even by lowering the Ce content down to 50 at.%, the solid solution between barium zirconate and cerate presents severe stability limitations in a wet atmosphere.⁴³

The highest power density outputs for H^+ -SOFCs using chemically stable $BaZrO_3$ -based electrolytes are around 250 mW cm^{-2} at 600°C ^{32,35}—still not sufficiently competitive with the performance of SOFCs based on oxygen-ion conducting electrolytes.¹

The performance of fuel cells based on Ca-doped $LaNbO_4$ as the electrolyte is even lower, mainly ascribed to the poor kinetics of several tested cathode materials¹³ and the lower protonic conductivity of this material compared to the best perovskites. In addition, the fabrication of a complete cell using $LaNbO_4$ avoiding detrimental phase segregation is very challenging. Unless these remaining issues are addressed, $LaNbO_4$ will not be the ultimate electrolyte choice for fuel cell applications. Concerning the LWO electrolyte, tailor-made anodes and cathodes with ASRs $\sim 0.3\text{--}0.5 \Omega \text{ cm}^2$ have been proposed,^{31,44,45} but electrode-supported fuel cells have not yet been tested.

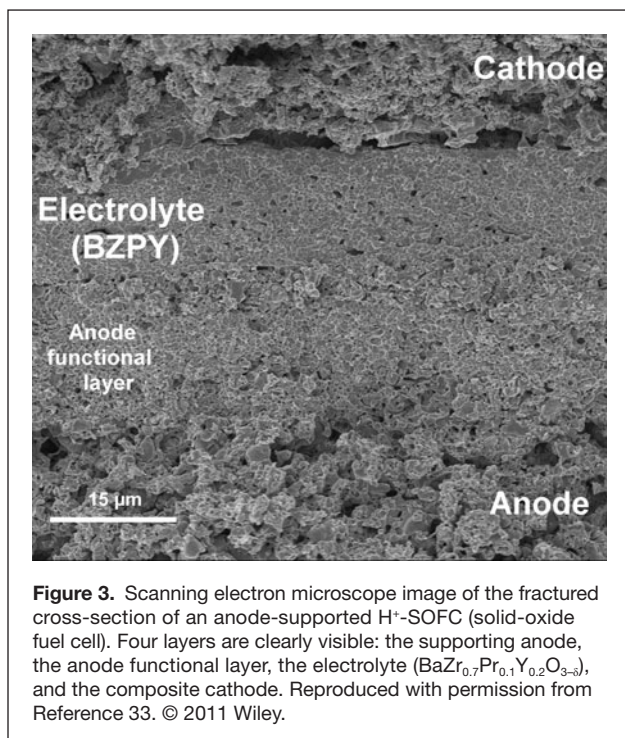

Figure 3. Scanning electron microscope image of the fractured cross-section of an anode-supported H⁺-SOFC (solid-oxide fuel cell). Four layers are clearly visible: the supporting anode, the anode functional layer, the electrolyte (BaZr_{0.7}Pr_{0.1}Y_{0.2}O_{3-δ}), and the composite cathode. Using different fuel cell designs, promising results for H⁺-SOFCs have been obtained by fabricating polycrystalline BZY freestanding membranes on Si chips by thin-film deposition and microfabrication technologies. A peak power density output of 186 mW cm⁻² at 450°C has been achieved.⁴⁶ These results, coupled with the high conductivity of BZY epitaxial thin films with reduced grain boundary regions, open new possibilities for the development of miniaturized H⁺-SOFCs.

Summary and perspectives

HTPC-sintered polycrystalline pellets, as well as highly ordered thin films, have shown conductivity values in the same range or even larger than those of the best performing (and chemically stable) oxygen-ion conductors at low temperatures. Moreover, composite cathode materials, mixed protonic and electronic conductors, specifically designed for HTPC electrolytes, have been developed showing comparable performance as the typical cathodes used for oxygen-ion conductors.

In spite of the good performance of the individual cell components, the power density output reported so far for H⁺-SOFCs is significantly lower compared to SOFCs based on oxygen-ion conductors. The reason for this relatively limited performance is not clear, but it might be due to poorer electrode kinetics, especially in the cathode. It must be highlighted here that research and development on H⁺-SOFCs is still relatively limited. Improved cell design and microstructural optimization may render the key solution. The good performance of the individual cell components holds the promise of obtaining larger power density output, and clearly indicates the need for more scientific and technological efforts for full exploitation of the potential of HTPCs.
